Abstract. Most marine larvae have a free-swimming phase before settling. This phase could be important for retention, dispersal, and connectivity. It was thought that coral larvae swimming capabilities were so poor that currents advected them. Nowadays it is accepted that coral larvae have some ability to control their position. This study describes, from laboratory observations, the swimming capabilities and changes in swimming behaviour with age of *Montastraea annularis* and *M. faveolata* larvae, and how these might promote or hinder dispersal. Three larvae from each species were observed and their position, swimming velocity, and behaviour were recorded every five minutes. GLM ANOVA was used to determine the effects of age on velocity and depth. To determine the effect of age on larvae behaviour a binomial logistic regression analysis was performed. The results show the capability of larvae to alternate swimming pattern, velocity and depth which enables them to explore suitable substrata for settlement. This capability can be used to control their position in the water column, and reduce or increase dispersal. Additionally, we found, for the first time 1) swimming velocity and depth varied with age for *M. annularis*; and, 2) the probability of settlement increased with age for both species.

Key words: swimming behaviour, larval age, larval dispersal, *Montastraea*

Introduction

Almost all marine invertebrates have free-swimming larvae (Young et al. 2002). Until recently it was widely assumed that while in the plankton, larvae were advected by currents as passive particles (e.g. Jackson 1986), and that the duration of planktonic larval stages were correlated to the dispersal distance (Strathmann 1985; Shanks et al. 2003a). Nowadays it is known that larvae can swim or change their behaviour avoiding advection (Byers, Pringle 2006). Thus, larvae can disperse further than predicted (Leis, Carson-Ewart 2003), or settle very close to their parents reducing genetic dispersal (Cowen et al. 2006). Swimming ability can also be crucial on searching for a suitable substratum on which to settle (Kingsford et al. 2002). The alteration in swimming behaviour during active searching for settlement sites is often in response to specific cues (e.g. Krug, Zimmer 2000; Baird et al. 2003; Hadfield, Koehl 2004).

Swimming capabilities vary among marine larvae. Reef fishes and decapod crustaceans are capable swimmers, overcoming in some cases local currents (Zeldis 1985; Luckenbach, Orth 1992; Leis, Carson-Ewart 2003). Coral larvae and cyphonautes larvae are examples of poor swimmers (e.g. Abelson 1997; Shanks et al. 2003b; Strathmann, Grünbaum 2006). Even weak currents move faster than coral larvae (Brooke, Young 2005). However, both capable and poor swimmers can avoid being adversely advected by currents by modifying their behaviour and controlling their position in the water column (Fuchs et al. 2004; Brooke, Young 2005). For coral larvae this behaviour appears to be mediated by the detection of water pressure (Stake, Sammarco 2003).

Larval life histories influence swimming behaviour and later settlement processes. In many cases, larvae can extend their time in the plankton but this has increased associated costs (Pechenik 1990). For lecithotrophic larvae these costs may be depletion of energy reserves and larval senescence (Pechenik 1990). Surprisingly little is known about changes in swimming behaviour as coral larvae age, and how these changes could affect dispersal. Mundy and Babcock (1998) found that five out of six species of coral larvae responded either to light quantity or quality. Additionally, they observed that competent larvae were more positive geotactic than non-competent larvae. In 2005, Brooke and Young reported that the larvae of ahermatypic coral *Oculina varicosa*, when fully developed, swam towards the surface in a spiral fashion.

Larvae of benthic organisms spend most of their time in the water column either searching for food

and/or a suitable substratum on which to settle. Studying the swimming behaviour is important to understand population ecology processes such as settlement, recruitment, and population composition (Mumby 1999). Before we can understand how dispersal is influenced by the swimming behaviour of the invertebrate larvae, is essential to determine the swimming abilities of planktonic larvae throughout the entire larval period. Using coral larvae reared in the laboratory, the aim of this study was to document changes in larval swimming behaviour (categories, velocity and depth) with age, and how these changes could promote or hinder dispersal from parental reefs. We hypothesised that changes in swimming behaviour will occur with age and that these changes would enhance settlement. We studied coral larvae from *Montastraea annularis* and *M. faveolata*, two of the most important reef builder species in the Caribbean.

Material and Methods

Gamete bundles of both *M. annularis* and *M. faveolata* were collected during spawning nights in 2004 and 2005 at San Andres Island (Western Caribbean, Colombia). After spawning, gamete bundles were transported to the laboratory where fertilisation was performed. Cross fertilisation was designed to avoid both self-fertilisation and fertilisation between different species. Self-fertilisation was avoided by separating eggs and sperm after gamete bundles were collected. Egg/sperm were separated using a 60 μm plankton mesh. The eggs were rinsed several times with fresh filtered and 90 ^{o}C heated seawater. Fertilisation between different species was avoided by keeping gamete bundles, eggs and sperm from each species in labelled vials. Coral larvae were reared following Pizarro et al. (2006).

When larvae were fully developed (Young et al. 2002) observations on swimming behaviour were performed. Larvae were placed into a cylinder (1 m high x 20 cm diameter) of transparent acrylic (3 mm thick) filled with sterilised seawater (Pizarro et al. 2006). A metric ruler was fitted to the exterior of the cylinder. Three larvae were observed daily, each for one hour, and vertical position (depth), swimming velocity (cm s^{-1}), and the type of swimming behaviour they were performing. These data were recorded every five minutes. Swimming categories were named after the movement the larvae performed (table 1).

To determine the effects of the age of the larvae on the swimming velocity and swimming depth, a separate repeated measures GLM ANOVA was conducted for each response variable. Because the response data were not normally distributed and not transformable a value of $\alpha = 0.001$ was taken as the level of significance (Underwood 1997). In both cases the data were not spherical, therefore Greenhouse-Geiser adjusted F values were used. For both analyses the within subject factor was age and the response was either velocity or depth.

To examine the effect of age on the behaviour of the larvae a binomial logistic regression analysis was used to predict the probability of settlement behaviour as a function of larval age. All upward swimming categories were associated with transport behaviour, while all downward swimming categories were associated with settlement behaviour. For the remaining swimming categories transport behaviour and settlement behaviour were determined by a combination of the observed swimming category of the larvae and the depth at which the swimming category was taking place. For example, horizontal swimming in the first 10 cm of the water column was recorded as transport behaviour, whereas, if it occurred any deeper it was recorded as settlement behaviour.

Results

Twelve different swimming categories were identified for *Montastraea faveolata* larvae, and eleven of the twelve were observed for *M. annularis* larvae (Table 1). The frequency varied within categories and between species (Table 1). While for *M. annularis* the most frequent category was swimming down (28.6 %), for *M. faveolata* it was snake swimming (38.91 %).

Table 1. Name and frequency (percentage of the total number of observations) for swimming and settlement behaviour (percentage for each swimming category) of the swimming categories identified for *Montastraea annularis* (*Mann*; n = 1287) and *M. faveolata* (*Mfav*; n = 897) larvae.

	Swimming (%)		Settlement (%)

[a] denotes the most frequent swimming category for each species

The frequency of each swimming category did not vary with the larvae age (Fig. 1). However the most commonly observed categories appeared to have a periodicity in both species (e. g. see first panel in Fig. 1 – swimming up category). Nevertheless, the snake swimming category for *M. annularis* was the only one

that seemed to change considerably with the age of the larvae (Fig. 1). For this particular category, the frequency increased with the age of the larvae until day 9, after which it was rarely observed.

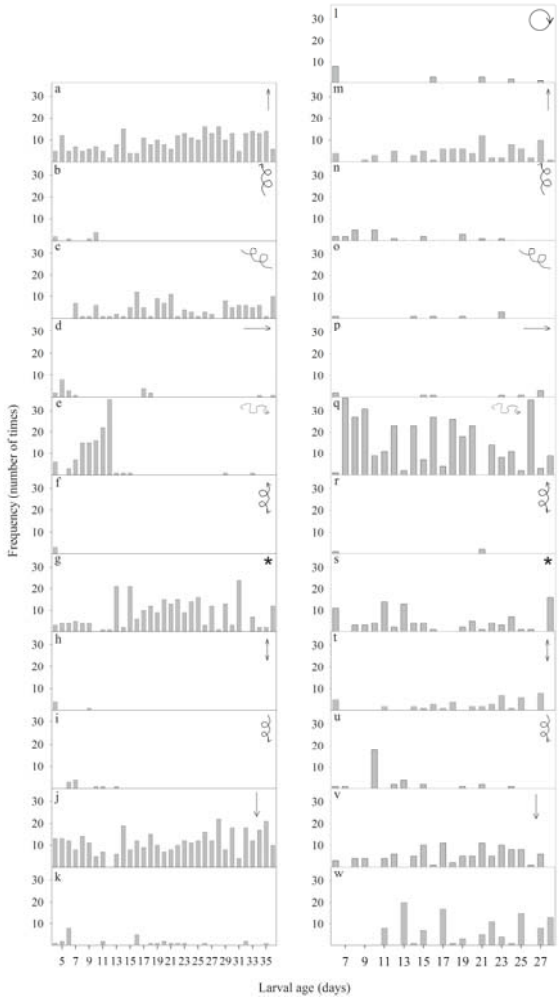

Figure 1. Frequency of each swimming category as a function of the age of the larvae for *Montrastraea annularis* (a-k) and *M. faveolata* (l-w). Pictograms identify behavioural category and are arranged in the same order as in Table 1.

Recorded swimming velocities (cm s^{-1}) for *M. annularis* were 0.01-1.4 and, 0.01-1.6 for *M. faveolata*. For *M. annularis* larvae swimming velocity and depth varied with age (repeated measures GLM SS_{vel} = 2.35; df_{vel} = 10.74; F_{vel} = 6.44; P_{vel} < 0.001; SS_{depth} = 158892.15; df_{depth} = 9.63; F_{depth} = 7.82; P_{depth} < 0.001). The larvae started to explore the water column from the first day they were fully developed. A plot of mean depth vs. day indicated that there was a periodicity in the variation of depth. Simple time series analysis using moving averages of between 2 – 4 d suggested that this periodicity was ~ 3 d (Fig. 2 a-c).

Swimming velocities of *M. faveolata* larvae did not change with age (repeated measures GLM SS = 7.30; df = 1.178; F = 2.00; P = 0.162), however depth of the larvae behaviour did change with age (repeated measures GLM SS = 488857.45; df = 5.126; F = 26.32; P < 0.001). 1 d to 5 d old larvae remained mostly at the surface and larvae between 6 d and 23 d old moved from the surface to deeper in the water column. A periodicity in the variation of the depth of ~ 3 d (Fig. 2 d-e) was also found for this species when applying a simple time series analysis.

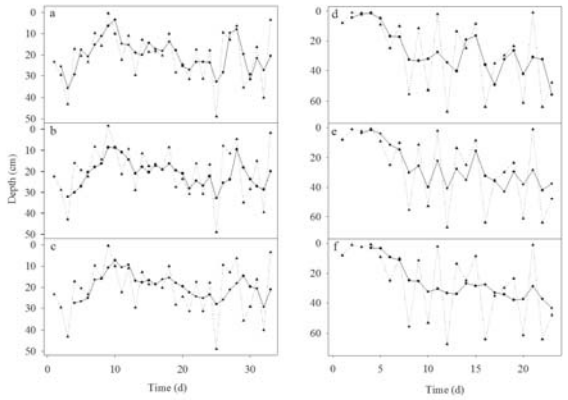

Figure 2. Mean depth of *Montastraea annularis* (a-c) and *M. faveolata* (d-f) larvae as a function of time (dotted line; *M. annularis* n= 33 and *M. faveolata* n= 23), and results of the moving averages for time series analysis (continuous line) for two (a, d), three (b, e) and four (c, f) days. Periodicity was determined by peak coincidence rather than amplitude

The probability of occurrence of settlement behaviour when compared to transport behaviour was 1.01 and 1.09 times higher with each day's increase in age for *M. annularis* and *M. faveolata* respectively (*M. annularis*: $P_{\text{settlement behaviour}} = 1/(1 + e^{-(-0.26 + 0.11 \text{ Age})})$, Odds ratio = 1.02, P < 0.001, Log-likelihood = G = 11.38, DF = 1, P < 0.001; *M. faveolata:* $P_{\text{settlement behaviour}} = 1/(1 + e^{-(-1.31 + 0.15 \text{ Age})})$, Odds ratio = 1.09, P < 0.001, Log-likelihood = G = 62.83, DF = 1, P < 0.001).

Discussion

This study shows for the first time that coral larvae have a range of different swimming behaviours and that 1) swimming velocity and depth of the larvae of *M. annularis* varied with age; and, 2) the probability of settlement-linked behaviour increased with age for both *M. annularis* and *M. faveolata*. The role of different swimming behaviours in pre-settlement processes of corals has only been studied somewhat superficially (e.g. Carlon, Olson 1993; Raimondi, Morse 2000). Furthermore, swimming behaviour and the relationship to transport and settlement have not been previously recognised (e.g. Morse et al. 1988;

Gross et al. 1992; Abelson 1997; Krug, Zimmer 2000; Raimondi, Morse 2000; Miller, Mundy 2003). It is common knowledge that most coral larvae are active swimmers (see Harrison, Wallace 1990). This study has clearly shown the capability of larvae to vary swimming pattern, velocity and depth which then enables them to explore suitable substrata for settlement. This capability is also likely to contribute to dispersal away from natal reefs by controlling their position in the water column (see Harrison, Wallace 1990), and may determine adult distributions on reefs (Raimondi, Morse 2000).

At least four (spiral, snake, still and circles) of the 12 swimming categories described in this study could be considered as contributors to the dispersal of larvae in coastal waters (Porch 1998). This suggests that the remaining categories of *Montastraea* spp. larvae (spiral up, spiral down, spiral up and down, down, and up and down) could be important for retention of larvae within natal reefs (Codling et al. 2004). In contrast, if larvae enter oceanic waters, then active swimming could play a role in maintaining depth to ensure maximum dispersion. Such modification of swimming behaviour has been associated with the capacity to control a vertical position in the water column, rather than as a dispersal factor (Raimondi, Morse 2000; Bassim, Sammarco 2003; Krug, Zimmer 2004). In this regard, the observations on the frequency of the swimming categories as a function of time for each species suggest that 1) *M. annularis* larvae would control their vertical position most of the time; and, 2) *M. faveolata* would be affected the most by superficial currents. To determine whether the swimming categories of both *M. annularis* and *M. faveolata* larvae are important in maintaining position in the water column near their natal reefs or in the ocean waters to be dispersed, it is necessary to develop local hydrodynamic models (Mumby 1999). These models would predict if embryos and pre-competent larvae are retained within the natal reefs or carried away from them. However, if larval development and swimming patterns in natural environments are similar to those observed in this study, it is feasible that both self-recruitment and dispersal occur (Sammarco 1996).

The changes in depth with age for both *Montastraea annularis* and *M. faveolata* could be an indication of an increased necessity to search for a suitable substratum on which to settle. These findings are similar to those described by Vermeij et al. (2006) for *M. faveolata*. In their study larval behaviour changed from phototactic to geotactic with age, however, they assessed the vertical movement of the larvae only in standard Petri dishes (∅ 9 cm) with approximately 1.5 cm depth. For some other invertebrates, larval distribution in the water column varies according to the larval development stage (Thiébaut et al. 1998; Krug, Zimmer 2004). Krug (2004) observed that swimming speed in trochophore larvae increased as they developed. Of interest is the periodicity in depth observed for both *Montastraea* species, suggesting a vertical migration in the water column. As a non-feeding larvae (Vermeij et al. 2006), this migration would not be related with/to the daily vertical feeding migration observed in plankton (Pearre 2003). Vermeij et al. (2006) also observed a vertical migration in *M. faveolata* larvae. The migration seemed to be a daily light/life cycle with higher movement at night. Nevertheless, their results have to be carefully analysed due to the use of shallow Petri dishes. Indeed, Marta-Almeida et al. (2006) demonstrated that larvae that do not show diel vertical migrations were affected by currents and upwelling leading to offshore transport. We propose that in *Montastraea* spp. vertical migration is a strategy to enhance both detection of suitable substrata for settlement and also increases the dispersal away from unsuitable substrata (Krug, Zimmer 2004; Ríos-Jara 2005; Marta-Almeida et al. 2006).

In lecithotrophic or non-feeding larvae, energy reserves decrease with larval age (Wendt 1996). For lecithotrophic gregarious organisms a desperate larva hypothesis was proposed in the 50s (Knight-Jones (1951, 1953) and Wilson (1953) reviewed in (Toonen, Pawlik 2001)). This hypothesis states that larvae become less discriminatory in their settlement choice when energetic resources decrease and occurs mostly in gregarious organisms, such as bryozoans and ascidians (e.g. Wendt 1996; Marshall, Keough 2003), and in some non-gregarious gastropods (e.g. Botello, Krug 2006). In all these cases larval metamorphosis decreased with time, and even when larvae could respond to cues and initiate metamorphosis older larvae were unable to complete (e.g. Wendt 1996; Toonen, Pawlik 2001; Marshall, Keough 2003; Botello, Krug 2006). This decrease in energy may influence coral larvae velocity and swimming patterns ultimately affecting population dynamics. The observed changes in swimming velocity and swimming patterns with larvae age in this study suggest that the 'desperate larvae' hypothesis could be applicable to both *M. annularis* and *M. faveolata* species. The results suggest that larvae differing in ontogeny can display different behaviours that could affect potential dispersal. Further studies on larval swimming behaviour would help to elucidate the role of these activities on larval retention and dispersion, as well as the importance for population dynamics.

Acknowledgment

We thank everyone who helped this study, especially M Novoa, P Herrón, MF Maya and JP Asmuss as well as the San Andres island campus of the National University of Colombia for allowing us to use their facilities. VP was partially founded by the Programme Alßan of the European Commission (E03D16973CO) and JCT by the Royal Society.

Abstract. Recruitment patterns of scleractinian and milleporan corals were investigated at Suva Harbour, Great Astrolabe Reef, and Taveuni. The lowest recruitment rate occurred at a site in Suva Harbour while the highest recruitment rate occurred on a reef periodically disturbed by high rates of sedimentation. Recruitment was >7 times greater in summer than winter with the greatest seasonal variation occurring in Acroporidae. Pocilloporidae, Poritidae, Faviidae and unidentified recruits had higher recruitment rates in deeper water while Acroporidae recruited primarily to shallow waters. The number of recruits from broadcast spawning acroporids was high, which was probably related to the high frequency of occurrence of the family. More than half (52%) of all recruits were acroporids.. Recruitment was unexpectedly high at a site with periodically high sedimentation levels. Seawater temperatures recorded during the study fell within the normal range for the area.

Key words: Acroporidae, planulae, Pocilloporidae, Poritidae, larva

Introduction

Fiji has one of the largest coral reef systems in the SW Pacific, with >1000 reefs. Although Fiji pos-sesses hundreds of kilometers of coral reefs that are an important source of food (Quinn & Kalangi 1998) and revenue for many people (Quinn & Davis 1998), little is known about coral recruitment processes on the reefs. Many of the ecological studies of corals in Fiji have been limited to species lists (Gawell & Seeto 1982) or surveys of bleached corals (Cummings et al. 2002). While recruitment patterns of juvenile corals are important to the overall community structure of coral reefs (Harrison & Wallace 1990), there have been no studies that examined the variation in recruitment of corals in Fiji.

This study looked at inter annual, seasonal, and geo-graphic variation in coral recruitment over two years and compared the results with other similar studies. Suspended sediment and subsurface temperature were recorded to document two factors that were considered likely to influence settlement.

Material and Methods

Survey sites

Suva Harbour (SH)

Suva Harbour contains the main port for the capital city of Fiji, Suva (Fig. 1). Two sampling sites were chosen in SH (18°07'S; 178°21'E). One was within the lagoon adjacent to the Suva Channel (SC) and the other, Fish Patch (FP), on the outer reef slope adjacent to the harbor entrance. The Suva Channel reef is near the main port in polluted water (Naidu & Morrison 1994, Davis et al. 1998), FP is in less pol-luted water, but has experienced *Acanthaster planci* infestation (Zann et al. 1990, pers. observation).

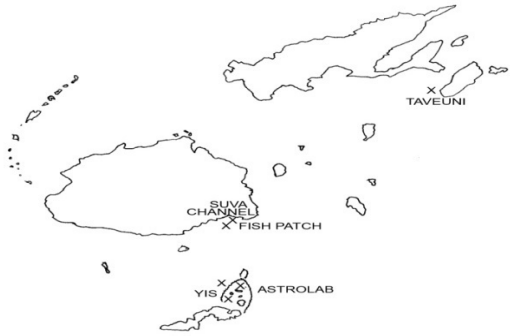

Figure 1. Sampling locations around Fiji.

Great Astrolabe Reef (GAR)

The Great Astrolabe Reef (8°45'S.; 178° 30' E) is an atoll situated 70km south of Viti Levu with a typical depth of 20m. The total human population of the villages on all the 13 islands within the reef is ~1000 people. There were three sampling sites at GAR. One was adjacent to one of the islands, Yanuyanu-i-sau (YIS) (18° 47'S; 178°30'E). YIS is a small, uninhab-ited island, <13.5 ha (Naqasima et al. 1992), that contained seven goats in 1996. The goats, put there years ago by people from the neighboring island, have eaten all of the leafy vegetation to a height of ~1.5m. Consequently, the island is bare of ground vegetation and during heavy rain from December to April the soil washes down the steep slopes onto the fringing reefs.

Taveuni (TA)

Taveuni (16°59'S.; 179°53'E.) (Fig. 1) is an island 200km north of Viti Levu. Except for a few small plantations and resorts, the island lacked any major commercial development.

Physical parameters

Suspended sediment traps 35cm long were constructed from 5.2cm (2") diameter PVC pipes. Paired traps were deployed at all sample sites. The traps were collected periodically between May 1996 and April 1998. Animals, shells, and macro detrital material were removed and the remaining material was dried at 60°C for 24 hrs. The net weight was cal-culated as mg cm^{-2} day^{-1} representing the mean value of each pair of traps.

A Hugrun underwater temperature recorder (UTR) with an accuracy of $\pm$0.05°C monitored subsurface seawater temperatures hourly at GAR from 2 October 1997 to 12 December 1998.

Coral recruitment

Benthic recruitment arrays were constructed using PVC pipe each with four terracotta tiles as described in Quinn and Kojis (2003, 2006). Arrays were deployed at two depths around FP (15m, 25m), one depth in SC (15m), and two depths at TA (15m, 25m). Arrays were placed at three sites in GAR: off the south western outer wall (15m), on a lagoon patch reef (5m) 100m from Dravuni Island, and on a fring-ing reef near YIS (5m, 15m). The arrays were installed in late March / early April 1996. Tiles were replaced in October / November 1996 ("winter 1996"), March / April 1997 ("summer 1997"), September / October 1997 ("winter 1997") and in April 1998 ("summer 1998") and collected about six months later. Numbers of coral recruits on the top, bottom, and edges were counted (standardized to number recruits m^{-2}) and identified to family where possible.

Factors such as orientation of the substratum (Birkeland et al. 1981, Wallace 1985), depth (Babcock 1988); availability of larvae (Harriott & Fisk 1987); interorganismal competition (Harrison & Wallace 1990), browsing herbivores, and dispersal patterns (Sammarco & Andrews 1988), affect recruitment and consequently community structure. The first two factors were standardized in the experiment.

Results

Physical Parameters

Suspended sediment traps were sampled a total of 106 times. The sedimentation rate at each sampling time ranged from <0.1 mg cm^{-2} day^{-1} at GAR from July to October 1996 to 104.9 mg cm^{-2} day^{-1} at YIS from December to April 1997. All of the sites recorded the highest sedimentation rate from December to April. The mean sedimentation rate was highest at YIS and was nearly twice the levels at FP 15m and SC, sites with the next highest sedimentation rates, and 7.5 times higher than the rate recorded from nearby YIS. TA had the lowest sedimentation rate. Sedimentation was most variable within the GAR lagoon sites.

The subsurface sea temperature (S^3T) at Great Astrolabe Reef ranged from 23.6°C in October 1997 to 28.8°C in December 1998 (Fig. 2). The mean S^3T was 26.2°C (CV=4.3%; N=10503). On 15 January 1998, a cyclone passed within 100km of the site and the S^3T dropped 1.1°C within one hour. The mean S^3T during summer 1997 was 26.7°C (CV=4.5%), winter 1998 was 25.7 °C (CV =3.7%) a difference of 0.9 °C.

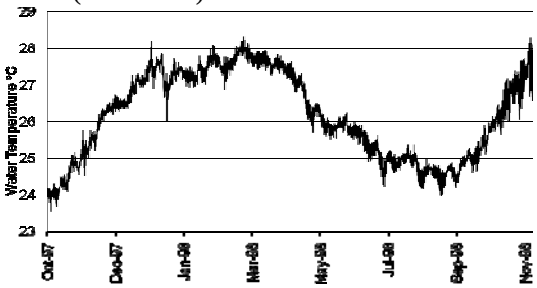

Figure 2: Subsurface seawater temperature at Great Astrolabe Reef

Coral recruitment

A total of 1628 scleractinian and 12 milleporan recruits settled on 72 tiles. The lowest recruitment was at SC (5 recruits m^{-2}, winter 1996) and the high-est at YIS (1749 recruits m^{-2}, summer 1997). Owing to the recruitment in summer 1997, YIS had the greatest total overall recruitment (3624 recruits m^{-2}). As expected the lowest total overall recruitment rate was at SC ($\bar{x}$=51 $\pm$SD 29 recruits $m^{-2}yr^{-1}$) and the highest recruitment rate was at YIS ($\bar{x}$=1812 $\pm$ S.D. 1275 recruits m^{-2} yr^{-1}). FP, 15m, had the next greatest recruitment. The shallow TA site had the third greatest recruitment. Except for the very low recruitment at SH, there was high mean recruitment at the sites (>323 recruits m^{-2} yr^{-1}).

Acroporidae dominated recruitment (52.2%), followed by Pocilloporidae (30.3%), others (13.0%), Poritidae (3.4%), Milleporidae (0.6%) and Faviidae (0.5%). There was a very large recruitment of Acroporidae at YIS in the summer of 1997 represent-ing nearly 30% of the total recruits. This was about double the amount that settled the following summer.

Recruitment rates for the different families varied with depth. Over 55% of the Acroporidae and 67% of the unidentified recruits recruited to the shallowest depth (5m) (Fig. 2). Most Pocilloporidae, Poritidae, Faviidae and others settled in deeper waters. Poritidae recruitment increased with increasing depth. Milleporidae almost exclusively settled at 15m. The rate of recruitment declined with increasing depth at most sites (Fig. 2): 5m - 271 recruits m^{-2}, 15m - 177 recruits m^{-2}, 25m - 142 recruits m^{-2}.

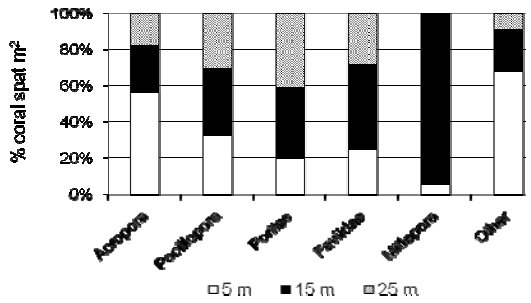

Figure 2: Percentage of coral family recruitment by depth

About six times as many coral spat recruited during the summer ($\bar{x}$=570; N=16; SD=519) compared to winter ($\bar{x}$=93; N =16; SD=101). A paired *t*-test was used to compare mean total corals for each site, there was a very highly significant difference in the rate of recruitment between seasons (*P*=0.0027; N=16). Recruitment was greater in the summer at every site (Fig. 3). The greatest difference was at YIS where recruitment was >10 greater in the summer. In contrast, the difference in the recruitment rate between summer and winter at TA was <10%.

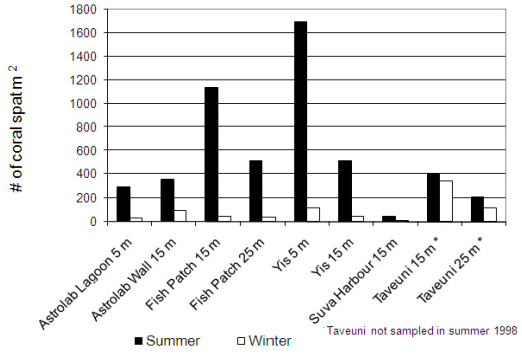

Figure 3: Total number of recruits m^{-2} by seasons and sites

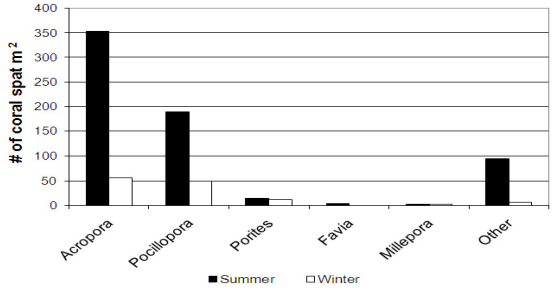

Figure 4: Number of recruits m^2 by family and season

The highest number of recruits were from the families Acroporidae and Pocilloporidae. Their recruitment rate was 7.1 and 3.9 times higher, respectively, in the summer than winter (Fig. 4). Using pooled 15m data a two way ANOVA was performed on the factors years and sites. The location factor was significant (P = 0.027; df = 4), but year was not (P = 0.161; df = 1).

The site with the greatest seasonal difference in Acroporidae recruitment (*t*=2.68; *P*=0.02, S) was YIS (Fig. 5). Seasonal recruitment differences for the Pocilloporidae (*t*=3.71; *P*=0.004; VS) were the great-est at FP (Fig. 6). Seasonal recruitment of Poritidae was variable (*t*=0.21; *P*>0.05; NS) with two sites recording more recruitment during winter than in summer (Fig. 7). The recruitment rates of both Mil-leporidae and Faviidae were much lower than other families. Faviidae recruited only in summer. Uniden-tified recruits, termed "other", settled seven times more frequently in summer than in winter (Fig. 8).

Discussion

The density of coral recruits at most sites in Fiji was higher than reported from other tropical sites using a similar sampling strategy (Kojis 1997, Quinn & Kojis 2002, 2003, 2008). The mean recruitment rate for summer (pooled across sites for summer 1997 and 1998) was $570m^{-2}$ (SD $\pm$ 519; N=9) compared with $31m^{-2}$ observed in Saipan; $0m^{-2}$, Rota; and $35m^{-2}$ Tinian in the Commonwealth of the Northern Mariana Islands (CNMI) in 1995 (Quinn & Kojis 2002) and $89\text{-}160m^{-2}$ in the eastern Caribbean (Kojis 1997). Even the mean winter recruitment ($93m^{-2}$) was over three times the "summer" recruitment recorded in the CNMI. The only Fijian site with a low recruitment rate was the turbid water site in Suva Channel. Davis et al. (1998) reported finding dangerously high levels of TBT in mollusks collected in Suva Harbour and other workers have reported on the pollution in the harbor (Naidu & Morrison 1994).

Several factors probably contribute to the high recruitment rate at most sites. Firstly, the sites were on reefs with high coral cover and a rich diversity of species. Secondly, there was an abundance of healthy, fecund reefs in close proximity releasing large amounts of larvae. The number of broadcast spawning acroporids recruiting was high and was probably related to the high frequency of occurrence of the family and the large numbers of larvae they produce.

The relative abundance of the various taxa of the recruits was similar to that reported from the GBR. Acroporid recruits were dominant in Fiji (52%) and in the Cairns region (16^{o} latitude) of the GBR (65%) followed by pocilloporids: 30% - Fiji and 25% - GBR, Cairns region (Fisk & Harriott 1990). The third most abundant group was the "other". More work is required to identify young spat of many families. Poritidae spat had a higher relative abundance (3%), then on the GBR at similar latitudes, (0%) (Fisk & Harriott 1990), but were less abundant (16%) than on an isolated sub tropical reef (Lord Howe Is., 31^{o}S) (Harriott 1992). We suspect this relates to differences in the relative abundance of adults of the family on the reefs at each location.

Coral recruitment was greater in the summer than in winter and this was consistent with the pattern for the GBR (Fisk & Harriott 1990). We hypothesize that most recruitment occurred during the main coral spawning season in October/November (Fiebig & Vuki 1998). However, brooding corals often have an extended spawning season (Harrison and Wallace 1990) and this is true of pocilloporid corals (Stoddart & Black 1985), which recruited in both winter and summer.

The high number of recruits on the Taveuni tiles, which were collected in November, was probably the result of the "winter" tiles still being deployed at the start of the summer spawning season for broadcast spawning species.

The reproductive life history of milleporan corals is poorly known. It is unclear whether the sporadic milleporan recruitment that was observed was due to random settlement of relatively few larvae or the unsuitability of the settlement surface for milleporan planulae.

The GAR sites represented communities that have developed within a very limited range of environmen-tal conditions. In addition to a narrow range of temp-erature, salinity, and dissolved oxygen, they are subjected to low sedimentation rates and concomitant low nutrient levels (Charpy et al. 1996). Chevillon et al. (1996) found no lithoclasts in the sediment of the GAR and concluded that there was limited terri-genous influence in the lagoon. However, none of their sample sites were within 1km of YIS, the site with the highest sedimentation rate. Sediment from soil erosion from the island is clearly evident at YIS.

While sedimentation has been shown to reduce fecundity in corals at depth (Kojis & Quinn 1984), the high sedimentation rate at YIS did not result in low recruitment rates. Although coral larvae are trans-ported between reefs (Fisk & Harriott 1990) as well as retained on the reef by water flow patterns (Black et al. 1991), it is unexpected that such high recruit-ment would occur on the site with the highest sedimentation rate. We suspect it is likely that this is because most of the sedimentation occurs during relatively short periods of high rainfall and, the effects probably dissipate rapidly, and do not affect reproduction. Also, there was no evidence of increased coral mortality or bleaching at YIS. The conservative mixing of reef waters within the lagoon, coupled with the synchronized mass spawning of abundant acroporids, may allow for greater fertile-zation success and retention of planulae resulting in higher recruitment rates. However, this does not explain the lower recruitment rates at the other lagoonal site near Dravuni within GAR. Given that the residence time for water mass in the GAR was 15 - 25 days (MacLeod

1992) and the sedimentation rate was lower at the other lagoonal site, one might reasonably expect a more uniform availability of larvae throughout the lagoon from at least broadcast spawning species and a more uniform rate of recruitment at both lagoonal sites.

Corals are known be have adapted to various levels of short-term exposure to sedimentation (Rogers 1983). Increased long-term sedimentation is generally associated with increased erosion associated with land modification or dredging and /or an increase in resuspended sediment. Chronic stress from sedimentation will result in lower coral fecundity (Kojis & Quinn 1984), lowering the number of larvae available for recruitment and reducing a coral reef community's ability to recover from natural perturbations. Additionally, the decreased water transparency associated with higher turbidity is known to reduce the depth range of species (Kojis & Quinn 1984) and cause bleaching and the death of corals (Rogers 1979). In the case of YIS, a reef receiving a high sediment load, the summer recruitment rate was about 3.5 times greater than at the two other GAR sites. Summer recruitment rates at the other two GAR sites were within 10% of each other.

Acknowledgement

We are grateful to the people of Dravuni Village for allowing us to study their marine resources. Funding for this project came from the University of the South Pacific University Research Committee, grant #6291-1311-70766-15 and the Tropical Discoveries Foundation. P Edmunds and P Newell kindly reviewed the paper and offered many useful suggestions. This work was written while NJQ was a J.W Fulbright Fellow.

Abstract. In the macro-tidal lagoons, of the Indian Ocean, coral reefs can be momentarily submerged by water at high tide and partially emerged at low tide. This process contributes to lagoon and open sea exchanges, although the reefs are often considered as impervious and the water fluxes assumed to occur only through the passes. To gain insight in spatial variability of fluxes at a reasonable cost that moorings alone cannot be able to provide, we develop an original experimental approach combining small ship side mounted ADCP measurement following transects thru passes and near reefs, with more classical high resolution ADCP moorings. This new strategy of measurement is exemplified at the occasion of an experimental campaign on the Mayotte lagoon and used after in Tulear lagoon. The results of this experiment are presented. Particularly, first, it is shown how the mounted ADCP data are made. A specific tidal analysis methodology is then proposed to get the spatial variability of the tidal component of the current thru the passes and above the reef. Then, all these analysis allow us to estimate the tidal induced fluxes thru the passes and above the reefs and to evaluate their respective part in water lagoon renewal.

Key words: measurement, tidal current, side mounted ADCP

Introduction

Tropical lagoons are impacted by climatic changes but also by direct anthropogenic activities. Water quality is directly related to water renewal time, which is regulated by passes and by the coral reef barrier. Possible reef modification (anthropic or intense climatic phenomena induced destruction, sudden stop of the suited general conditions for their edification, water level increase) could have major consequences on the functioning of reef-lagoon. To be able to forecast the reef tolerance versus modifications of the lagoon functioning conditions, it is needed to understand the hydrodynamic regulation induced by these reef barriers and the possible evolution of their regulating effects.

At some meso or macro tidal lagoons of the Indian Ocean, the water that is over running above the reef strongly tidally modulates fluxes through passes. The Mayotte lagoon and the Tulear lagoon, situated in the Mozambique Channel, are examples of meso-tidal reef lagoons. The pronounced tidal character of these lagoons generates peculiar hydrodynamics, which depend upon the tidal cycle.

In this study, it has been decided to focus on the cross reef tidal fluxes on the Mayotte lagoon and the Tulear lagoon. Our aim is to know the influence of the reef hydrodynamic control on the open seawater exchanges and on the lagoon dynamics, as well as to compare flux above coral reef and through passes.

In order to gain insight into spatial and temporal variability of fluxes at a reasonable cost that moorings alone are not able to provide, we have developed an original experimental approach. This approach combines small shipside mounted ADCP measurement following transects with more classical high-resolution ADCP moorings. This experimental strategy will be first presented, and then the specific analysis methodology will be described. In the third part, results will be presented and discussed, mainly, the tidal induced fluxes through passes and above reefs, as well as their respective part in water lagoon renewal**.**

Field experiment

Study site

The field observations were performed at the Tulear lagoon and at the north-east lagoon of Mayotte located in the Mozambique Channel. The north-east lagoon of Mayotte constitutes the north-eastern part of a wider lagoon extended to the south. These two

lagoons that are located in same broad geographical area, are submitted to a quite similar external tide, dominated by the semi-diurnal wave M2.

Even if their orientation is opposite, their morphology is similar. They are about a 10nm long and 1nm to 5nm wide, opened at two passes of about 1 to 2nm. The north pass of the Mayotte lagoon and the south pass of the Tulear lagoon are the less wide (1nm) and the deeper ones (50m at the Mayotte lagoon; 20m at the Tulear lagoon). These lagoons are partially closed to the Mozambique Channel along the long reef. The Mayotte reef is a well-developed fringing reef whereas the Tulear reef is mainly a sand and mud covered, dead reef. Its topography is broken with crest and moat. Even if the geological origins of this reef, the external aspect or the width are different, their influence in the flow control seems to be the same. At high water, the reef is submerged (2-3m at the Mayotte lagoon), whereas the reef is weakly immerged (50 cm at the Mayotte lagoon) or emerged (at the Tulear lagoon) at low water.

However, the Mayotte lagoon is deeper (about 20m) than the Tulear one (about 10m), and the nature of entrance water varies with lagoon. At the Tulear lagoon, the incoming flow is usually constituted by water from the Mozambique Channel, but sometimes, due to external condition such as wind, a weak quantity of fresh water from Fiherena and Onilahy Rivers could enter. At the Mayotte lagoon, the incoming water could be either Mozambique Cannel water (entering through the north pass and above the reef) or lagoon water from the south lagoon (entering through the south pass).

Sensor deployment

Our observations were performed from 2006, November 9th, to 2006, November 24th, at the Mayotte lagoon and from 2007, September 9th to October 12th at the Tulear lagoon. To obtain spatial and temporal variability of hydrodynamics, we deployed moorings on which ADCP were installed and associated hull-mounted ADCP measurements. To investigate the flow through the pass and above the reef, we conducted a field survey along pass and along the reef.

Moorings deployment:

At the Mayotte lagoon, the north pass is divided in two channels. One ADCP was moored in each channel. The third was moored in the south pass and the last one, along the reef. At the Tulear lagoon, the south pass is divided in two channels as well. One ADCP was moored in each of them, the third one in the north pass. Because of technical problem, the last one was not moored along the reef, but in the middle of the lagoon. Finally, in each lagoon and during each campaign, four ADCP were deployed at locations indicated in Fig 1. In order to compare the velocity measured with moored ADCP and with side mounted ADCP, the cell had been set to 1m. About ten cells were obtained for each ADCP.

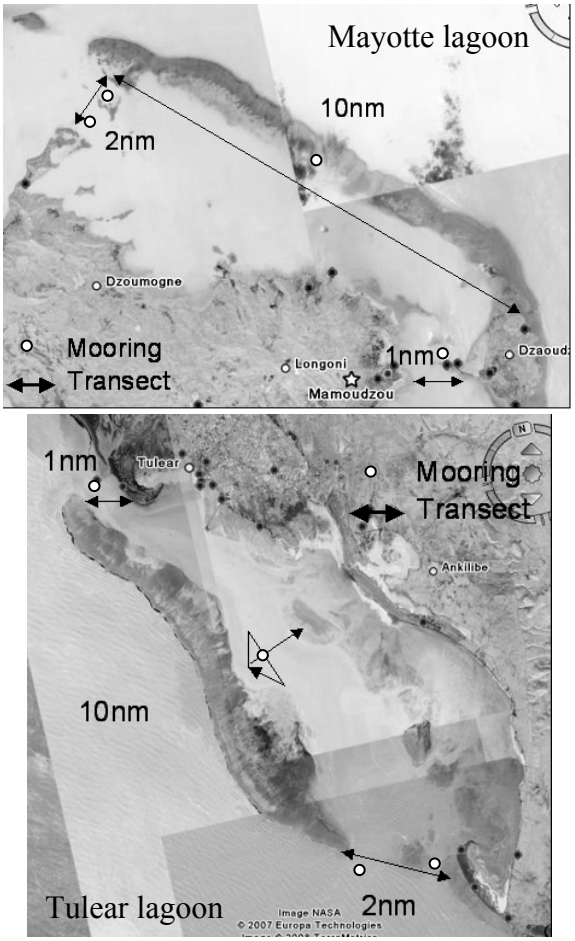

Figure 1: Study site (Mayotte lagoon and Tulear lagoon) and sensor deployment

In order to lighten the ADCP deployment field, the ADCP was fixed into a red plastic box weighted with concrete bloc. With only two divers and a small boat as a zodiac, this mooring can be deployed. Even with this rudimentary aspect and with velocity able to reach 2m/s, these moorings had been stable and a mooring set for tests did not move for more than 6 months.

Description of transect:

As is usually done to measure currents in rivers, the ADCP was set up on a boat with a tubular stainless steel frame along the inflatable fender. In low waves and with a boat velocity of about 3 knots, measurements were in good agreement with measured velocity mooring. Then, to associated data from the side mounted ADCP with those from mooring and to

quantify fluxes, transects were made near moorings, along passes and along the reef barrier (at the Mayotte lagoon) or in the middle of the lagoon (at the Tulear lagoon) as presented in Fig 1.

Data description

The tide is mainly semidiurnal with a fluctuation spring and neap tide. The campaign duration was chosen to measure this variability. In Mayotte, the tidal amplitude is about 2m during the spring tide and 0.5m during the neap tide. In Tulear, the tidal amplitude is weaker, about 1.50m during the spring tide and 0.25m during the neap tide.

Velocity at moorings was obtained in the two lagoons. The Mayotte campaign was quite short in time and measurements were only performed during 10 days. But, the Tulear campaign was much more optimized and moored measurements were far longer (until 50 days). During the November Mayotte campaign, at the end of the rainy season, the sea was quite calm, while, during the October Tulear campaign, the sea was rougher, but transects could be performed. Then, velocity-measurements along transect were successful, but due to technical problems some data had not been acquired.

Velocities are quasi-barotropic; their main direction is cross-pass or cross-reef at the boundaries and along-shore in the middle of the lagoon. Velocities are correlated to the tide. Periodograms can reveal the mean periodic waves. The main water level tidal waves are M2, S2 and K2 in Mayotte and mainly M2 and K2 in Tulear. The velocities are modulated by these waves, but other harmonics of M2 or S2 can be observed (notably, waves with a period of 6h).

The side mounted ADCP gives spatial information about the velocity along the pass. These measurements reveal variability due to the topography of the bottom.

Data processing.

The side mounted ADCP gives a spatial information velocity, however not synoptically. Indeed, the transect duration can take 1 hour. Notably, due to the tide effect, the velocity varies during this hour. Then, it is hard to compare velocity measured at the beginning of transect with the one measured at the end without treatment. So to treat this spatial information, the velocities have to be estimated for the same time for each transect. For this purpose, the temporal information of the mooring can be used to obtain temporal information at each point all along the transect.

Spectral analysis of mooring data

At the mooring station, named M_0, the measured velocity, is not the real velocity, but an approximation: $\hat{u}(M_0) = u(M_0) + \varepsilon(M_0)$, with ε, the measurement error with a blank noise and $u(M_0)$, the complex representation of the velocity: $u(M_0) = \|\vec{u}(M_0)\| e^{i\theta(M_0)}$. Supposing a linear decomposition, the velocity can be decomposed into a periodic signal, u_{tide}, mainly linked to the tide and a non-periodic signal, $u_{res}(M_0)$:

$$u(M_0) = u_{tide}(M_0) + u_{res}(M_0).$$

The main frequencies of velocity waves can be deduced from the periodogram. Then, a classical harmonic analysis can allow reconstructing the tidal signal of this velocity.

$$u_{tide}(M_0) = \sum_{k=1}^{N} A_{M_0}(\omega_k) e^{i\omega_k t + \varphi_k}$$

with ω_k, $\varphi_k(M_0)$ and $A_{M_0}(\omega_k)$ the pulsation, the phase and the amplitudes for wave k and N the number of waves which depends on the tidal dynamics of area studied.

Wave amplitudes can be approximated by $A^*_{M_0}(\omega_k)$ with minimizing, by the least square sense, the equation:

$$u(M_0) - \sum_{k=1}^{N} A_{M_0}(\omega_k) e^{i\omega_k t + \varphi_k}$$

Hence, the approximated tidal velocity at M_0 location, $u^*_{tide}(M_0)$, and the approximated "residual velocity", $u^*_{res}(M_0)$, are written:

$$u^*_{tide}(M_0) = \sum_{k=1}^{N} A_{M_0}(\omega_k) e^{i\omega_k t + \varphi_k}$$

$$\text{and } u^*_{res}(M_0) = u(M_0) - u^*_{tide}(M_0)$$

$u^*_{res}(M_0)$ represents not only the measurement errors or harmonic analysis approximation, but also all velocity component not represented with the harmonic analysis as velocity due to wind effect or non-represented tidal wave, for example. Hence, the approximated velocity at M_0 is:

$$u^*(M_0) = u^*_{tide}(M_0) + u^*_{res}(M_0)$$

Temporal and spatial data processing

As identical transect were repeated along the campaign, many instantaneous data can be obtained in one location. The method proposed here is an expanded version of Candela et al. 1992 and Garcia-Gorriz et al., 2003. The main difference being that their method was developed in meso-scale region and not in coastal region and contrary to the both technical; our strategy uses a reference mooring. As for the velocity at the mooring, velocity at each point of the transect, named M, is assumed to be expanded

in two types of components: time periodic and non-periodic component. Both are spatially variable. Then, equations analogous to the equation for the velocity at mooring, can be written at each transect location, M. Hence:

$$\hat{u}(M) = u(M) + \varepsilon(M),$$

with $\hat{u}(M)$ the measured velocity in M location, $\varepsilon(M)$ the measurement error estimated to about 5cm/s and $u(M)$ the real velocity. Then, the velocity is decomposed as tide-induced velocity, $u_{tide}(M)$, and "residual velocity", $u_{res}(M)$:

$$u(M) = u_{tide}(M) + u_{res}(M).$$

The aim is to estimate the tide-induced velocity and the "residual velocity". For that, as Candela et al, 1992 and Garcia-Gorriz et al, 2003, we assume that the time-periodic part of the equation can be expressed as the product of amplitude, and a sinusoidal function of time.

$$u_{tide}(M) = \sum_{k=1}^{N} A_M(\omega_k) e^{i\omega_k t + \varphi_k(M)},$$

with $\varphi_k(M)$ and $A_M(\omega_k)$ the phase and the amplitudes for the wave *k* at the location M. N is the number of waves which depends on the tidal dynamics of area studied and which is the same as for the velocity at the mooring.

$A_M(\omega_k)$ and $u_{res}(M)$ are functions depending on the location of M. Here, *s,* the distance from the mooring, characterizes the location: Candela et al, 1990 show that the quality of the fit was not strongly dependent on the choice of the function. Thus, the horizontal functions $A_M(\omega_k)$ and $u_{res}(M)$ are prescribed and we chose them to be polynomials. They are based in both velocity at the mooring location and along transect with no other dynamical assumption involved, and are expanded as

$$A_M(\omega_k) = A^*_{M_0}(\omega_k).P_k^{(n)}(s)$$

$$\text{and } u_{res}(M) = u^*_{res}(M_0).Q^{(m)}(s)$$

with $P_k^{(n)}(s)$ and $Q^{(m)}(s)$ polynomial expressed as:

$$P_k^{(n)}(s) = \sum_{p=1}^{n} \alpha_{p,k} s^p$$

$$\text{and } Q^{(m)}(s) = \sum_{p=1}^{m} \beta_p s^p,$$

where $\alpha_{p,k}$ and β_p are the constants to be fitted to the observations and n and m the degree of the polynomials.

Setting,

$$J(\alpha_{p,k}, \beta_p) = \left\| \sum_{k=1}^{N} A^*_{M_0}(\omega_k).\left(\sum_{p=1}^{n} \alpha_{p,k} s^p \right) e^{i\omega_k t + \varphi_k(M)} + u^*_{res}(M_0).\sum_{p=1}^{m} \beta_p s^p - \hat{u}(M, t) \right\|^2$$

$\alpha^*_{p,k}$ and β^*_p are defined as the values minimizing J.

Then, the approximated tidal and residual velocity at M location, ($u^*_{tide}(M)$ and $u^*_{res}(M)$), are written:

$$u^*_{tide}(M) = \sum_{k=1}^{N} A^*_{M_0}(\omega_k).\left(\sum_{p=1}^{n} \alpha^*_{p,k} s^p \right) e^{i\omega_k t + \varphi_k(M)}$$

$$\text{and } u^*_{res}(M) = u^*_{res}(M_0).\sum_{p=1}^{m} \beta^*_p s^p$$

Hence, the approximated velocity at M is:

$$u^*(M) = u^*_{tide}(M) + u^*_{res}(M)$$

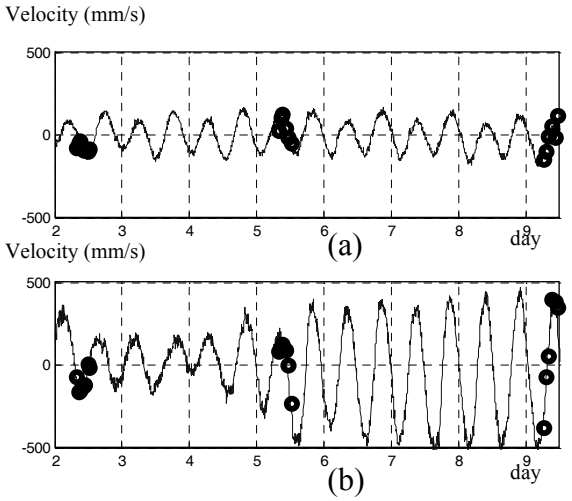

Figure 2: Measured velocity (black points) and calculated velocity (black line) in the middle of the south pass of Tulear lagoon. (a) represents the east component and (b) the north component.

As Garcia-Gorriz and al (2003), a systematic criterion was used to select the degrees of the polynomial. This test computes the error and the correlation when increasing the degree of polynomial functions. Hence, sequential tests with increasing polynomial degree values are run and the choice is made at the step when correlation tends towards 1 and errors displays small variation for higher degrees. The degree of the polynomial functions in the equation depends on the circulation in the studied area. Moreover, if M_0 is located on transect, $\alpha^*_{0,k}$ and β^*_0 are set to 1. Fig. 2 illustrates the reconstituted velocity in one point with the mooring velocity and in-situ data.

Results and discussion

Velocity

The resulting velocities are in accordance with measurement. The correlations with data are quite good (around to 0.9) and the error is weak (between 3 and 4 cm/s). The resulting velocity provides the main features of the velocity in passes. In the Tulear lagoon, the velocity is almost homogenous and follows the bathymetry. Contrarily, at the south pass of the Mayotte lagoon, the velocity is much more complex and this data process can point out the eddy in front of the north pass (Gourbesville and Thomassin, 2000). Fig. 3 illustrates the velocity at the Mayotte lagoon and the Tulear lagoon.

Flux

Spatial and temporal informations of velocity allow calculating fluxes. During the tidal campaign, in Mayotte, a mean flux of about 3000m^3/s entranced from the north pass whereas a flux of 2000m^3/s above the reef and of 1500 m^3/s through pass went out from the lagoon. At the Tulear lagoon, the flux went out through pass with a quantity of 1000 m^3/s and 2000 m^3/s. Hence, the water renewal times were respectively 7 and 4 days.

Conclusion:

A new strategy of data acquisition and a new data processing development to obtain spatial and temporal variations of current was developed. This methodology can provide spatial and temporal hydrodynamics information at reasonable cost. This data processing associates mooring and side mounted ADCP and evaluates the through-pass velocity with polynomial functions whose coefficient depends on the velocity at the mooring. Then, results can be extrapolated without any transect and the presented measurements allow calculating entrance lagoon flux. Moreover this boundary description allows the building of a numerical model that will be used to compute the residence time of water masses.

Abstract. The U. S. National Oceanic and Atmospheric Administration (NOAA) Integrated Coral Observing Network (ICON) Project uses artificial-intelligence software to implement heuristic models of coral reef ecosystem response to physical conditions. These models use if-then rules to recognize patterns in environmental data integrated in near real-time from multiple sources. One model is described to detect episodic, biologically significant fluxes acting upon coral reefs in the Florida Reef Tract. Data are gathered from *in situ* sensors and satellites for three sites near the reef crest: Sombrero Key in the Middle Keys, Molasses Reef in the Upper Keys, and Fowey Rocks off Miami. The model recognizes apparent circulation changes that may impact reef ecology. Criteria are *in situ* sea-temperature variability at near-tidal frequencies, wind velocity variability, and color-derived satellite chlorophyll *a* point data. Model ecological forecasts (*ecoforecasts*) are verified using secondary data not input to the model, including satellite ocean-color imagery, radar-derived ocean surface currents, and divers' reports. Events are characterized as being one of wind-driven upwelling; net transport of eutrophic water from outside the FRT; and interaction of Florida Current frontal features with reef topography, possibly modulated by internal wave-breaking. Multiple events are characterized in a 42-month period in 2005-2008.

Key words: coral reef • NOAA • chlorophyll • eddies and vortices • tidal mixing

Introduction

The Florida Reef Tract (FRT) encompasses the third largest barrier reef system in the world (FKNMS, 2001). Offshore, the Florida Current (FC) flows through the Straits of Florida after interacting with marine environments and ecosystems throughout the Caribbean Sea and the Gulf of Mexico. Meanders of the FC and mesoscale eddies interact with sloping topography in and offshore of the FRT (Lee et al. 2002). Smaller-scale vortices and coastal waves inshore of the FC front (Shay et al. 2007), and various upstream rivers (Hu et al. 2004, 2005) are also observed to interact with the reef as well. Finally, the Keys island chain is crosscut from the north by shallow channels, which episodically admit waters onto the back reef of the FRT from the West Florida Shelf (WFS) and outer Florida Bay (Smith and Pitts 2002; Lee et al. 2006).

The dynamics of circulation between the WFS, the FRT, and the terraces and deeper waters of the Straits can be highly complex, as are the biological responses of the reef ecosystem to the resulting fluxes of allochthonous water. These complex interactions can impact water quality as well as the marine ecology of the Keys, with important implications for coastal resource management within the region. Improvements in the characterization of these interactions are critical to the scientific understanding of nutrient dynamics and larval recruitment on the FRT. These processes, in turn, have important economic and ecological consequences, with potentially significant impact on tourism and commercial fishing interests.

An important tool for understanding this complex system is the Sustained Ecological Research Related to Management of the Florida Keys Seascape (SEAKEYS; Ogden et al. 1994) network of automated monitoring stations. These stations are installed upon navigational structures along the length of the FRT, providing a permanent infrastructure for continuous monitoring of meteorological and hydrographic environmental conditions. Three of these SEAKEYS stations, Sombrero Key, Molasses Reef, and Fowey Rocks, are located immediately inshore of the outer reef crest in the Middle and Upper Keys, providing a valuable base from which to

observe physical interactions between the FC front just offshore, and the shallow basin of the back reef just inshore. Furthermore, two of these stations, at Sombrero Key and Molasses Reef, are also suitably positioned to monitor hydrographic and ecological effects due to fluxes from the WFS and outer Florida Bay through the bridge channels of the Florida Keys.

Data

All SEAKEYS stations transmit data hourly in standard C-MAN format, via NOAA geosynchronous operational satellites. These transmissions are archived by the NOAA National Data Buoy Center (NDBC), and are analyzed in near real-time at NOAA's Atlantic Oceanographic and Meteorological Laboratory (AOML). The data reported by each SEAKEYS station includes hourly mean wind speed and direction, depth-averaged *in situ* sea temperature, and in some cases, *in situ* salinity, tidal height, or sea-surface Photosynthetically Active Radiation (PAR). The archived SEAKEYS data provide a nearly continuous record of these environmental variables, stretching in some cases as far back as 1987 (NDBC 2008).

The ICON Project has worked with collaborators at University of South Florida's College of Marine Science, Institute for Marine Remote Sensing (USF 2008) to integrate remote sensing data from the satellite-borne MODIS and AVHRR instruments. These products are geo-located and subsetted to each individual monitoring station location, to allow direct integration in time and space with *in situ* data. They provide high spatial resolution (order of 1km) data on sea surface temperature (SST) and ocean-color derived chlorophyll *a* concentrations, downloaded to NOAA AOML within 12 to 24 hours of measurement and indexed to individual reef sites.

Methodology

These integrated data streams are analyzed by AOML. They are evaluated using expert-systems software and heuristic if-then rules developed at AOML (Hendee et al. 2001, 2008) for both quality control, and for the presence of environmental conditions that may have an impact on the coral reef ecosystem, on the marine environment, and on important maritime economic activities in the region. The outputs of these if-then models are ecological forecasts (called *ecoforecasts*). This suite of data-integration, quality control, and near real-time monitoring techniques is the basis for the present study.

Statistical processing is then applied to the raw environmental variables, to derive time series of indices that can be used to directly assess certain hydrodynamic and biological conditions at the monitoring site. The primary index used to indicate increases in biological productivity on the reef over periods of one to three days is chlorophyll *a* concentration (chl_a). The USF-CMS chl_a product provides numerical estimates in $mg \cdot m^{-3}$, based on near real-time analysis of Terra and Aqua MODIS ocean color measurements. In this complex environment there is large uncertainty in the absolute value of chl_a, but here it is used as a relative index to show spatial and temporal patterns. High spatial-resolution time series of satellite chl_a for each of the three SEAKEYS sites have been derived for the sample period of 2005-2008. These time series are then filtered using quality control procedures similar to those used by the ICON Project for other types of *in situ* data. Peaks of this quality-controlled chl_a that fall above the 80^{th} percentile for the entire record at each site are then flagged as indicators of change in biological productivity at that site.

For each hourly average sea temperature value in the SEAKEYS *in situ* record, a simple subsample of the values from the prior 24 hours is collected, and the standard deviation of this sample is calculated. A 3-day simple moving average is applied to smooth this *sea temperature variability* time series. This procedure is intended to filter for episodes of sustained variance in sea temperature near inertial and dominant tidal frequencies. Such events include sustained anomalies, where either unusually cold water (Fig. 1) or unusually warm *and* cold waters (Fig. 2) are circulated onto the reef. One possible cause for near-tidal period, high-variance, *cold* events is the breaking of baroclinic tides (internal waves) on the reef slope (Leichter et al. 1996, 2003). When a meander or vortex associated with the FC has previously transported cooler waters to the base of the reef slope, such internal waves can transport and mix those waters up the reef slope. A likely cause of horizontal-mixing (warm *and* cold-anomaly) events is action of the barotropic tide interacting with shallow reef-crest topography. Periods of high chl_a (see above) that do not also correspond to periods of high sea temperature variability are flagged by the expert system as being of particular interest, as these may indicate instances where nutrients of more localized origin are causing a spike in productivity.

Wind velocity is also analyzed to distinguish events of anomalously high chlorophyll *a* concentration and/or high sea temperature variability that can be attributed to wind-forcing, as opposed to other proximate causes such as tidal mixing and frontal interaction with reef topography. Individual zonal and meridional wind vector components are derived from each hourly *in situ* wind-speed and direction measurement. Three-day subsamples of these U_{10} and V_{10} component values are then collected for each hour of the record, and a standard deviation of those

subsamples is calculated. The result is intended to provide an hourly index for *impulses* of substantial wind stress forcing that are of sufficient magnitude and duration to produce anomalously high wind-driven (shallow-water) currents in the back-reef, and/or wind-driven upwelling events on the fore-reef slope and reef-crest.

Results

Ecoforecasts were produced by the heuristic model independently for each of the three monitoring sites, for each day between 2005 Jan 01 and 2008 Jun 30 when statistically significant high sea temperature variability was indicated. Output for each ecoforecast included three components: 1) all antecedent data values (chl_a in $mg \cdot m^{-3}$, sea temperature variability index, wind impulse index); 2) a numerical indicator of the relative intensity of the forecast ecological response, called a Stimulus/Response Index (S/RI; Hendee et al. submitted); and 3) a series of symbolic codes indicating the attempted classification of each ecoforecast according to *dynamical mechanism* (wind-forced or non-wind forced), and *productivity* (sea-temperature variability coincident with high chlorophyll, or not).

Second, where a significant ecoforecast was produced for multiple days in a row at a given site, ecoforecasts were grouped together into an extended *event*. An attempt was then made to verify the dynamical mechanisms forecast for each event using synoptic satellite imagery of the Straits of Florida (Fig. 3), and where available, 1km-resolution ocean surface current vector fields derived from WERA High-Frequency radar (Shay et al. 2007). These images and fields were then further examined to characterize the regional scale of such events and any translational motions apparent in the associated phenomena, such as visible vortices offshore of the reef crest, or extended plumes of high chlorophyll *a* and turbid water inshore in the back-reef.

At Sombrero Key Reef, 44 such events were confirmed in the sample period, comprising 273 individual days of high sea temperature variability. At Molasses Reef only 28 events totaling 108 days were observed. Finally, at Fowey Rocks, the site furthest downstream relative to the FC, 38 events comprising 133 days of high sea temperature variance occurred.

The dynamical mechanism indicated by the ecoforecasts also showed significant variability between sites, with wind velocity variability strongly indicated as a forcing mechanism for 32% of all events at Molasses Reef, but only 21% of events at both Sombrero Key and Fowey Rocks. Overall, sea temperature variability events were at least partially coincident with high chlorophyll *a* concentrations 80% of the time across the three sites. Finally, although it was beyond the scope of the present study, periods of high chl_a concentration were also noted where there was *no* significant sea temperature variability. These also showed variability of incidence between sites – but with Sombrero Key showing significantly lower correlation between sea temperature variability and chl_a than the other two sites did.

Discussion and Conclusion

The pattern of spatial variability in the results is suggestive of possible differences in the dynamical regimes operating at each reef site. Sombrero Key is a site that is believed to be subject to periodic, persistent and significant influence from WFS, due to its proximity to the relatively large Moser Channel beneath Seven Mile Bridge. It is also a site where mesoscale vortices, long-period surface wave activity, and dominant wind forcing during much of the year may all be favorable to upwelling and up-mixing of nutrients from deeper FC waters offshore.

Molasses Reef by contrast is a site where the angle of the reef-crest isobaths to wind stress forcing differs by approximately 45^{o} from that at Sombrero (Lee et al. 2002). This cyclonic bend in topography, together with horizontal broadening in offshore isobaths, may also explain why this and other Upper Florida Keys sites are subject to relatively less mesoscale and sub-mesoscale cyclonic vorticity than Lower Keys sites (Fiechter et al. 2008). This is significant as such vorticity is also a potential forcing mechanism for upwelling of cool water and nutrients when it interacts with steep reef slope bottom topography.

The angle between reef crest isobaths at Fowey Rocks and the wind vector is shifted still further, by approximately 90^{o} relative to Sombrero Key. Compared to the isobaths at Molasses, however, bottom topography offshore of Fowey is also relatively steep, more like that at Sombrero. These facts are represented in our results, both by the intermediate frequency of events, and by the relatively low incidence of those events where wind was implicated as a dominant forcing mechanism.

Overall, the heuristic modeling approach is a powerful mechanism for monitoring and interpretation of both historical and near real-time environmental data on coral reefs. Furthermore, the indices chosen for the ecoforecast model described in this text, while kinematical and categorical, still appear to provide some valuable insights into the dynamical regimes operating on and affecting those reefs. Future work using these tools, coupled with additional data such as radar-derived surface currents, ship data, and numerical models of the mesoscale and sub-mesoscale circulation patterns on the reef, should bear still richer fruits.

Finally, these ecoforecasting tools are seen to have the potential to serve up useful information on marine conditions and reef ecology – to researchers, natural resource managers, and the public. Such information, made available in near real-time via the Web (ICON, 2008), can represent a unique perspective on the fragile ecosystem of the reef, and human use of it.

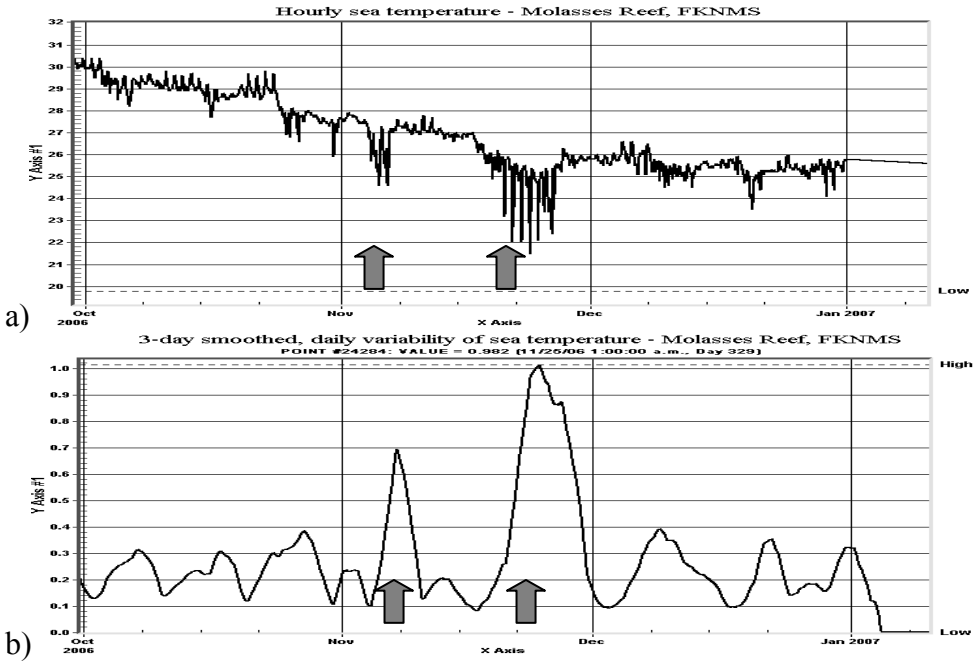

Figure 1: Cold-water anomaly (panel a) and associated peak in sea temperature variability index (b) associated with a likely upwelling event. Note that use of a realizable time-series filter in the variability index means it may lag raw sea temperature changes by one or more days.

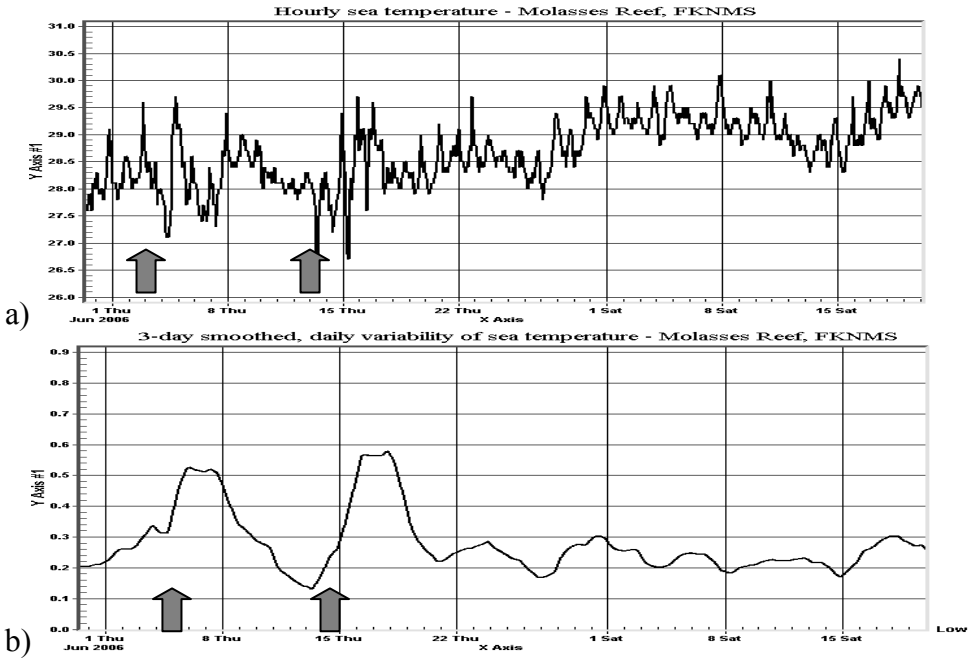

Figure 2: Sea temperature (a) and sea temperature variability index (b), showing a pair of events likely due to horizontal mixing of warmer (back-reef) and cooler (offshore) waters across the reef crest.

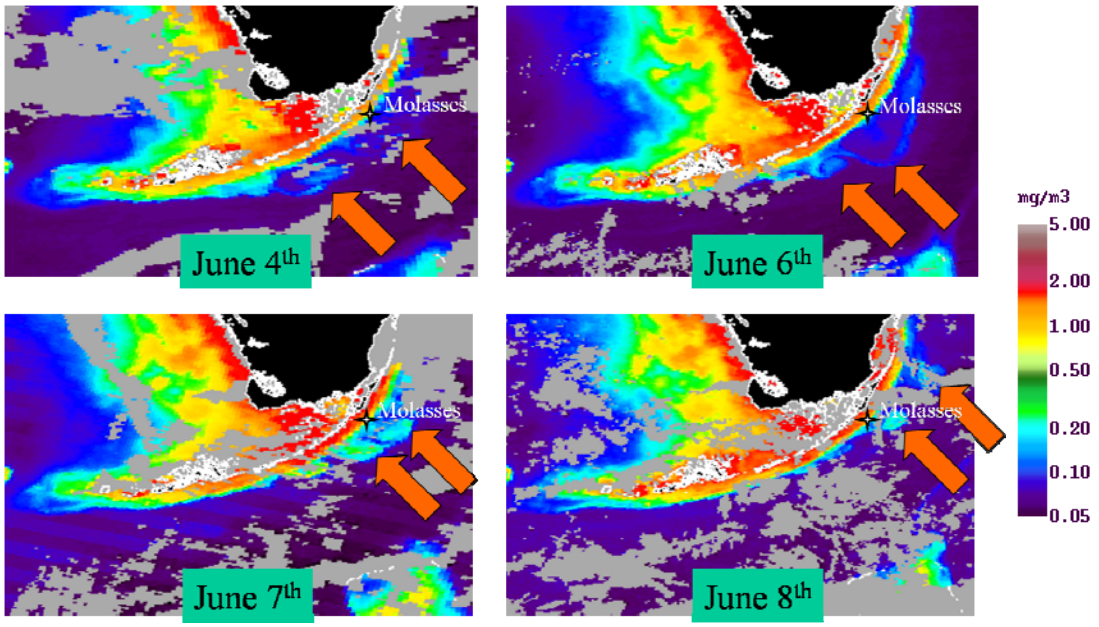

Figure 3: Sequence of MODIS satellite ocean-color images, showing chlorophyll *a* concentrations and associated circulation patterns in the Straits of Florida from 2006. Grey regions indicate cloud cover. Note the pair of vortices (arrows) translating past Molasses Reef over the four-day period, and interacting with one another and the inshore topography as they pass. These were among approximately 800 images examined visually in response to sea temperature variability ecoforecasts produced by the system described in the text, and served as visual confirmation both for the events, and the likely forcing mechanisms associated with each.

Acknowledgments

NOAA's Coral Reef Conservation Program and the High Performance Computing and Communications office are gratefully acknowledged for support of the ICON Project and related research. The authors also wish to thank Drs. L. K. Shay, D Manzello, C. N. K. Mooers, J. Leichter, and others for their insightful comments on some of the assumptions and conclusions involved in this research. Any errors however, are of course solely attributable to the authors.

Influence of Florida Current frontal eddies on circulation and fish recruitment around the Florida Keys Reef Tract

H.S. Kang, V.H. Kourafalou, C.B. Paris

RSMAS, University of Miami, 4600 Rickenbacker Cswy., Miami, FL 33133, USA

Abstract. The coastal seas around the Florida Keys Reef Tract exhibit complex dynamics resulting from the interaction with the Loop Current/Florida Current system and the frontal eddies that interact with the complex reef topography. Nesting to a succession of coarser, regional model and finally to basin-wide and global models allows the downscaling of large scale flows to scales of reef related processes. A high resolution (~900m) of the Hybrid Coordinate Ocean Model has been developed for the Florida Keys (FKEYS-HYCOM).

Florida Current frontal eddies are important mechanisms for the interaction of nearshore and offshore flows. They enable upwelling in the vicinity of the Reef Tract and influence transport and recruitment pathways, as they carry waters of different properties (such as river-borne low salinity/nutrient-rich waters) and waters containing larvae from upstream source, or entrained from nearby spawning grounds. FKEYS-HYCOM simulates both mesoscale and submesoscale eddy passages during a 2-year simulation period (2004-2005), forced with high resolution/high frequency atmospheric forcing. Coupling with the ecological population connectivity BOLTS model (BiOphysical Lagrangian Tracking System) allows simulations of larval transport, taking into account not only the dispersion of active physical larvae, but also the interaction of factors influencing larval survival, habitat selection and condition at settlement.

Key words: Florida Current frontal eddies, larval transport, Reef Tract, FKEYS-HYCOM, upwelling

Introduction

The ocean circulation around South Florida is dominated by the Florida Current, which originates where the Loop Current enters the Straits of Florida from the Gulf of Mexico, subsequently becoming the Gulf Stream as it emerges in the South Atlantic Bight (Fig. 1). The Florida Bay is openly connected to the Southwest Florida Shelf along its wide western boundary, but exchange with the Atlantic coastal zone of the Keys is restricted to a few narrow passages between the Keys island chain. Freshwater runoff occurs along the Ten Thousand Islands area through a series of small rivers (Fig. 1). Loop Current eddies propagate southward along the outer edge of the Southwest Florida Shelf and develop into persistent eddy structures off the Dry Tortugas.

The Keys coastal zone consists of a narrow, curving shelf with complex topography associated with its shallow Reef Tract. The outer shelf region of the Keys is dominated by meanders of the Florida Current and the downstream propagation of eddies.

The Florida Current frequently forms cyclonic, cold-core frontal eddies along the Slope and Shelf. These eddies are formed along the western edge of the Florida Current and travel northward along the continental margin.

Recirculation within mesoscale eddies and their several months' duration in the Keys coastal zone have been proposed as a retention mechanism that may contribute to local recruitment of larvae spawned in the Dry Tortugas or along the outer Reef Tract (Lee et al. 1992). Off the Florida Keys, frontal eddies are associated with cross-shelf larval transports (Sponaugle et al. 2005).

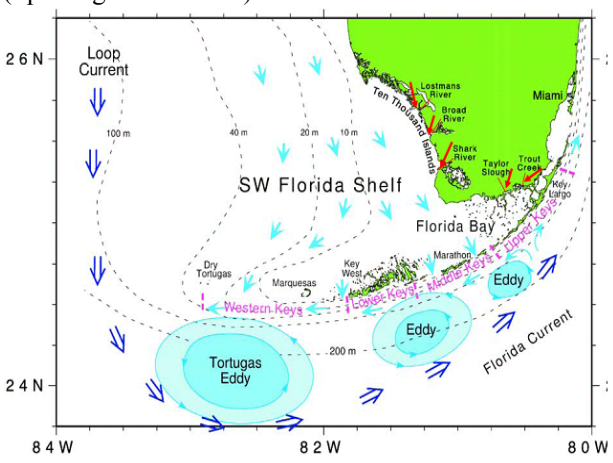

Figure 1. The complex South Florida coastal system, adapted from Lee et.al (2002). Red arrows mark the river sources.

A nested modeling approach has been employed to ensure the proper representation of the complex south Florida coastal system (Fig. 1). A high resolution (~900m) application of the Hybrid Coordinate Ocean

Model has been developed focusing on the circulation around the Florida Keys (FKEYS-HYCOM). Nesting to a succession of coarser, regional models (South Florida SoFLA-HYCOM and Gulf of Mexico GOM-HYCOM) and finally to basin-wide and global models allows the downscaling of large scale flows to scales appropriate for the study of reef related processes.

Model domain and set-up

The Florida Keys HYCOM model domain covers 79.0°W to 83.4°W and 22.8°N to 26.1°N (Fig. 2) with very high resolution of about 900m in horizontal and twenty-six hybrid-layers in vertical. It is being nested within the 1/25° SoFLA-HYCOM (Kourafalou et al. 2008) with daily updating for barotropic and baroclinic boundary conditions. Time integration steps are 30 sec for the baroclinic mode and 1 sec for the barotropic mode.

The topography is derived from the 2-minute NRL DBDB2 global dataset with a minimum depth of 2m. The FKEYS-HYCOM is forced with three-hourly wind stress, air temperature, atmospheric humidity, heat fluxes and precipitation from the 27-km horizontal resolution Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS, Hodur 1997; Hodur et. al 2002) for the year 2004 and 2005.

River runoff from the Shark River in the domain is the important source of low salinity which can impact the water property inside/around Florida Bay and along the Florida Keys through the neighboring Keys passages. It was prescribed as a line source of fresh water input along the Ten Thousand Islands starting from the Shark River. Low salinity waters from the SW Florida Shelf reach the AFKS through the Keys passages, influencing water properties along the Reef Tract.

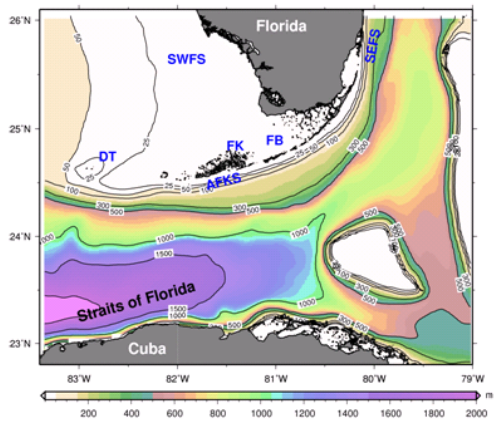

Figure 2. The Florida Keys (FKEYS) model domain and bathymetry (contours in m). It covers the Southwest Florida Shelf (SWFS), the Southeast Florida Shelf (SEFS), the Atlantic Florida Keys Shelf (AFKS) and the Strait of Florida, extending from Cuba to the Biscayne Bay. (FB: Florida Bay, FK: Florida Keys National Marine Sanctuary, DT: Dry Tortugas Ecological Reserve).

Evolution of eddies in the Straits of Florida

The Okubo-Weiss parameter is employed to quantify eddies and their propagation along the Florida Current front. This parameter represents a balance between the magnitudes of vorticity and deformation (Veneziani et al. 2005). Since the Okubo-Weiss parameter typically assumes highly negative values inside coherent vortex cores, while it becomes highly positive in the area immediately surrounding the vortex cores, it is very useful in identifying vortices and rotating structures, like eddies in the ocean. It measures the relative contribution of deformation and vorticity in a velocity field. Taking into account the characteristics of two-dimensional flow fields, eddy cores can be identified as the simply connected regions with high negative values of the Okubo-Weiss parameter. This parameter was used to identify and track eddies from altimeter data (Isern-Fontanet et al. 2003 and Cruz Gomez and Bulgakov 2007).

It is given by $Q = d^2 - \zeta^2$, where ζ is the relative vorticity field which is defined as

$$\zeta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}$$

and d is the deformation rate whose squared value is defined as

$$d^2 = \left(\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y}\right)^2 + \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right)^2$$

A series of 6-hourly maps of Okubo-Weiss parameter for 2004 has been prepared to identify and track eddies in the domain. One eddy (known as the Tortugas Eddy) appears on May 29 and becomes well organized as it moves along the shelf (Fig. 3). Its evolution is shown along with isobaths of 100m and 200m in black lines. Green lines mark 20°C isothermal lines at 150m to capture the Florida Current frontal boundaries (inner and outer). Variability of eddy strength and shape happens within these boundaries. As the eddy moves, it becomes elongated with smaller eddies embedded.

Some of the simulated eddies are captured by SeaWiFS chlorophyll-a images distribution. A big eddy south of Key West is present both in the SeaWiFS chlorophyll-a distribution and the FKEYS simulation. Also a chain of sub-mesoscale eddies along the Keys bounded by the 100m isobath line are shown (Fig. 4).

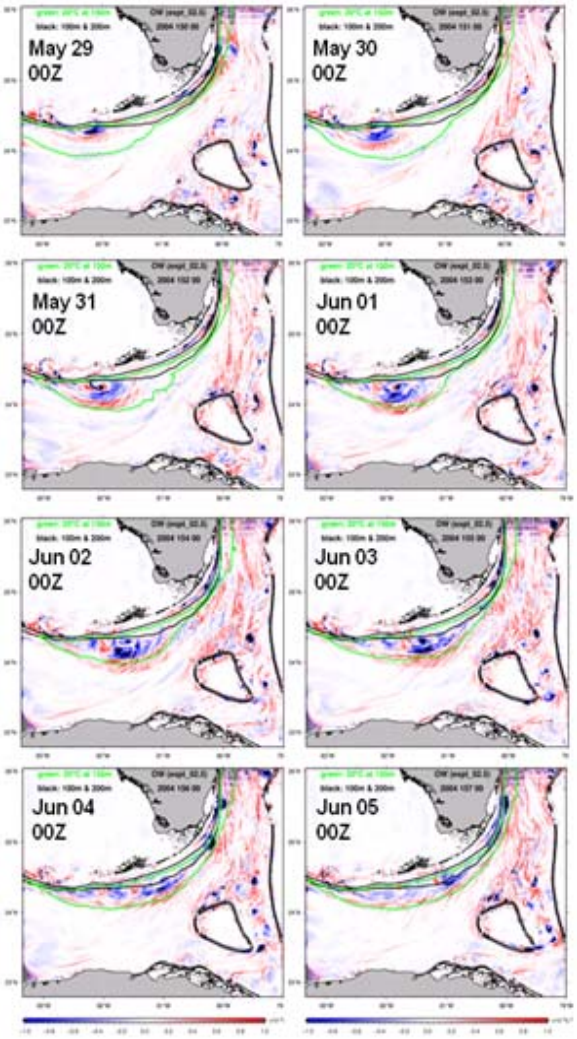

Figure 3. A series of daily Okubo-Weiss parameter maps from May 29 to Jun 5, 2004. Black lines are for 100m and 200m isobaths. Green lines are contour lines of 20C at 150m.

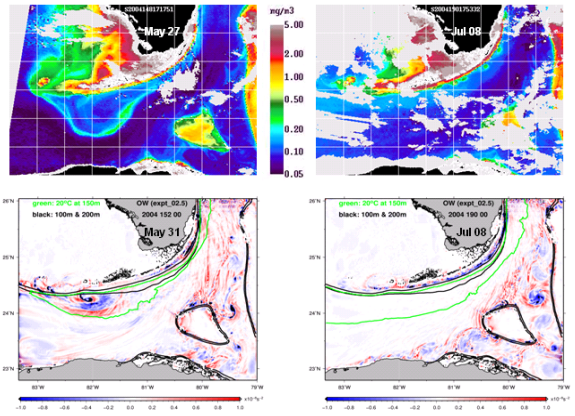

Figure 4. Distributions of Chlorophyll-a on May 27 and Jul 8, 2004 are shown on the upper panels while HYCOM-FKYS simulated Okubo-Weiss parameter maps on May 31 and Jul 8, 2004 on the lower panels.

Eddy induced Upwelling

A mesoscale eddy occurs near the lower part of the Florida Keys Reef Tract (see the top fourth picture in Fig. 5). Cross-sectional distributions of simulated temperature, salinity and along-shore velocity along the western edge of the eddy (82°W) show the upwelling of cool waters, impinging upon the Florida shelf. Strong positive velocities indicate the eastward flowing Florida Current, while velocities turn cyclonically to westward in the vicinity of the eddy.

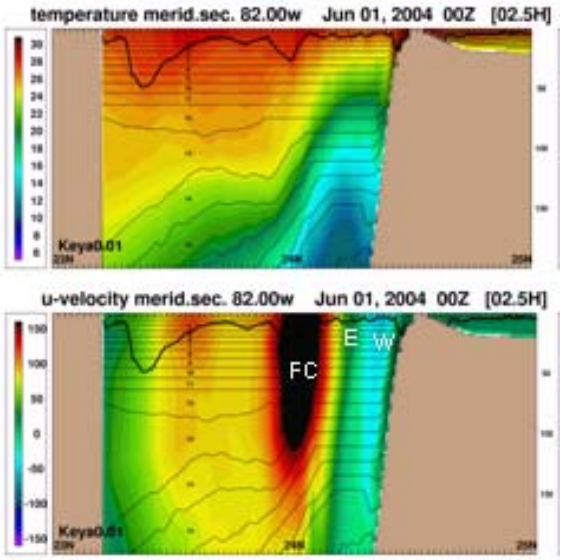

Figure 5. Cross-sectional distributions of simulated Temperature (upper) and along-shore Velocity (lower) during an eddy passage along 82.0°W on June 1, 2004.

Biophysical Lagrangian Tracking System (BOLTS) coupled with FKEYS-HYCOM

Coupling with the ecological population connectivity BOLTS model allows simulations of larval transport, taking into account not only the dispersion of active physical larvae, but also the interaction of factors influencing larval survival, habitat selection and condition at settlement (Paris et al. 2007). This probabilistic modeling system is composed of multiple standalone code units (i.e. biological seascape, ocean general circulation modules) coupled in a single Lagrangian stochastic unit. Of particular interest is the flexibility of the biological module in integrating any type of organism's life history traits, stochastic and spatially explicit larval mortality, larval vertical migration, and larval settlement behavior through the perception of suitable settlement habitat via coupling of the seascape module. In addition, BOLTS runs very efficiently in parallel processing within a LINUX PC Cluster environment and generates various types of output files, including individual larval trajectories and probability transition

matrices of individual larvae migrating from a source to a receiving population.

Passive 30-day near surface advection of larvae released at a single location in the Dry Tortugas computed with the BOLTS model is shown in Fig. 6, where random walk has been added on the FKEYS hydrodynamic model velocity fields. Trajectories and particle distribution integrated over the 30-day period show looping trajectories and accumulation of particles into small eddies (see orange-red particles). This result shows that eddies are an important mechanism of larval transport and delivery.

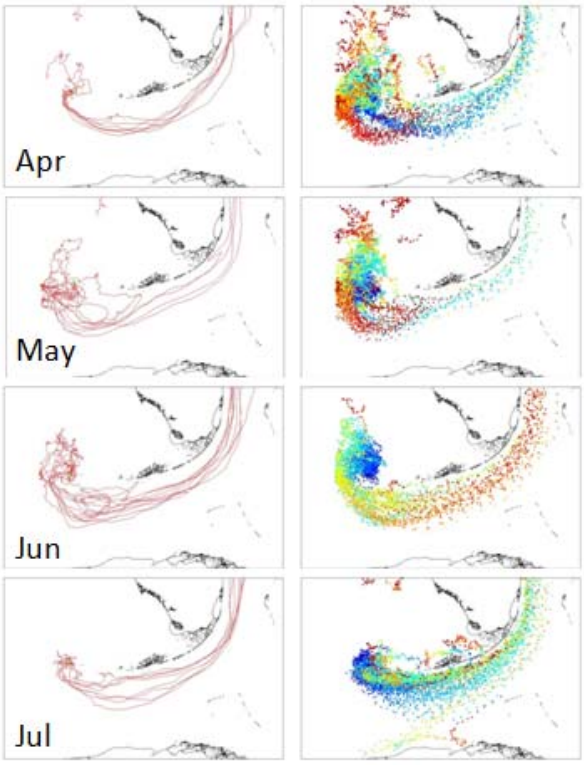

Figure 6. Passive scenario using 6-hour output of the FKEYS-HYCOM 2004: Monthly 30-day trajectories (left – a maximum of 10 trajectories are shown for clarity) and transport of 100 individual particles integrated over 30 days (right) released in the upper 5 m at a single location in the Dry Tortugas Ecological Reserve (green start). Color-code of the particles indicate their age from day 1 (blue) to day 30 (red). Areas with blue and cyan particles indicate strong advection, while areas with concentration of red particles represent retentive flow and/or the end of the 30-day advection.

Acknowledgement

This study was supported by the National Science Foundation (#OCE 0550732) and by by the Office of Naval Research and the National Ocean Partnership Program (#N000140510892). Chlorophyll-a images were provided by Chuanmin Hu from University of South Florida. The BOLTS code has been optimized by Ashwanth Srinivasan from the Center for Computational Science (CCS) of the University of Miami.

Use of the Coral-sel Technique in the Study of Small Scale Water Flow Environments on Coral Growth

C.L. Margolin

University of Miami, Rosenstiel School of Marine and Atmospheric Science, 4600 Rickenbacker Causeway, Miami, FL 33140, USA

Abstract. When flow experiments are carried out in open flow-through systems, several non-targeted variables may also change with varying flow rate, including temperature, oxygen level, and food availability. In order to keep these factors constant across flow treatments, it is necessary to place all corals into a single water system while still exposing them to different flow rates. In order to accomplish this, a rotating "coral-sel" was constructed at the University of Miami's Aplysia Resource Center. The coral-sel allowed corals to experience specific flow rates based on distance from the center of rotation while being immersed in a common water system. Clod card techniques were used in order to test differences in flow rates at each of the specified distances prior to attachment of coral to each position. Fragments of *Montastraea faveolata* were studied during pilot experiments. The coral-sel allowed observations of the effects of water flow on growth, zooxanthellar activity, and morphological characteristics of corallites. Preliminary findings show that water flow alone can influence a coral's growth in terms of surface area, weight gain. Additionally, flow influenced the photosynthetic activity of symbiotic zooxanthellae.

Key words: water flow, coral, growth, photosynthesis.

Introduction

As sessile organisms, the water that surrounds and moves over coral serves a number of important functions that assist in maintaining their existence. These functions include the delivery of dissolved gases and nutrients. Surrounding waters also provide zooplankton and particulate material that the coral may use as sources of heterotrophic nutrition. Additionally, moving water serves to remove harmful chemicals and waste products. Gaining an accurate understanding of the ways in which water flow rates influence coral's health and growth rates will allow for better prediction of the ways that coral, in both natural and artificial habitats, may behave under a variety of flow conditions.

As water moves past an object, a momentum boundary layer forms due to fluid viscosity. The thickness of the boundary layer is inversely related to the speed of water flow past an object (Patterson et al. 1991). The exchange of dissolved materials in and out of the coral is influenced by water motion, largely due to the effects of water motion on the formation and density of this boundary layer and the related influences on diffusion rates of materials through it (Patterson 1992; Patterson and Sebens 1989; Patterson et al. 1991; Bruno and Edmunds 1997; Gardella and Edmunds 1999; Gardella and Edmunds 2001; Kuffner 2001). Water flow rate and its influence on boundary layer thickness and exchange of dissolved materials can influence metabolic rates of coral and the symbiotic zooxanthellae contained within their tissues. Water flow can influence the rates of respiration, photosynthesis, and calcification of corals (Dennison and Barnes 1988). Water acts as a source of nutrition by providing essential chemicals as well as zooplankton for heterotrophic feeding. In this way, water flow can impact coral growth and survival through its influence on the prey capture method and success of coral colonies (Abelson, Miloh et al. 1993; Helmuth and Sebens 1993; Johnson and Sebens 1993; Helmuth et al. 1997; Sebens et al. 1998; Piniak 2002).

The manner in which differing water flow rates and boundary layer thicknesses will influence growth rates and/or morphological development of coral is species specific (Helmuth and Sebens 1993; Bruno and Edmunds 1997; Helmuth, Sebens et al. 1997). In order to accurately determine the influence of the water flow rate and the associated boundary layers on coral growth, it is necessary to reliably isolate water flow as the only variable in an experiment. This is a difficult task using standard laboratory or field methods.

In addition to the effects of water flow experienced under "ordinary" conditions, recent studies have found that increased water flow rates can temper the severity of the damage caused by a variety of stresses on corals. For example, the negative effects of

increased temperatures and photoinhibition can be alleviated by water flow in species and locally specific manners (Jones, Hoegh-Guldberg et al. 1998; Nakamura and van Woesik 2001; Nakamura et al. 2003; Nakamura et al. 2005). Given the current concerns about coral survival under changing climate and water chemistry conditions, gaining a better understanding of any factor that could alleviate stress on these animals may provide valuable information for preservation practices.

Investigating the effects of flow on coral growth under current water chemistry conditions and those predicted to occur in the future, will serve a two-fold purpose. First, by determining the flow conditions that are most conducive to coral growth and survival under current water chemistry conditions, we will be able to create more efficient coral nurseries. These nurseries may in turn serve as a source of coral for both scientific experimentation and reef restoration. This will minimize possible deleterious effects of these activities on natural populations.

Secondly, we may be able to determine the conditions best suited to preserving coral in natural areas under current and possible future water conditions. We would then be able to choose areas that fit these conditions to be set aside as marine protected areas. These protected areas may serve as refugia and possible source populations for corals during the stressful conditions likely to occur in the coming years.

In the past, most flow studies have been carried out either in natural habitats or controlled flumes. In natural habitats, a multitude of factors may vary between study sites. In most flume-based studies of flow effects on coral growth, the partition of treatments into separate systems can be a source of dissimilarity in factors other than the intended study variable. Changing the speed of water movement in an open or flow through flume system may lead to differences in temperature, nutrients, and oxygen levels experienced by each experimental colony. In order to remove this source of error, a research method was needed that allowed all experimental fragments to be exposed to the same conditions, yet still experience different flow speeds.

This paper introduces a new method of research and its possible uses and benefits in flow investigations.

Material and Methods

The method that was devised to reduce the difficulties mentioned above was the "coral-sel". This consists of a rotating structure that can hold a number of corals within a single water tank, but allows the attached corals to experience flow rates that vary based on their distance from the structure's center of rotation

The prototype coral-sel (Fig. 1) was constructed at the University of Miami's Experimental Hatchery and placed in an outdoor circular (3.7 m diameter) tank. The coral-sel consisted of a rotating column with ten arms at five separate heights (each level separated by 15 cm). The positions of the arms around the central axis of rotation were staggered to minimize possible effects of the movement of one plate or arm on a coral at any other position.

Each arm was approximately 95cm in length from the center of rotation, and held three ceramic tiles (experimental units) along its length (Fig 2). Tiles were placed at distances of 15, 50, and 85 cm from the center of rotation. This allowed the experimental units to experience water flow rates of 4.7 +/- 0.5cm/s, 15.7 +/- 1.4 cm/s, and 26.7 +/- 2.4 cm/s when the coral-sel spun at 3 rpm.

A large bicycle wheel was attached to the top of the central rotation column in a horizontal position. The wheel rim was lined with rubber to create friction for the chain that would cause it to turn. A table was positioned along-side of the tank that held a PVC frame attached to a wooden base that held a second bicycle wheel (with tire and gears) horizontally and held on an axle. The frame allowed the wheel to spin freely. A series of bicycle chains were connected to create a single chain long enough to connect the gears on the balanced tire and reach around the outside edge of the rubberized tire on the coral-sel. The frame also held a ½ horsepower motor with the spindle placed in contact with the outside edge of the balanced tire. When the motor was activated, the balanced tire spun at 32 rpm. Use of the attached gears allowed the rotational speed of the coral-sel to be adjusted to the desired 3rpm.

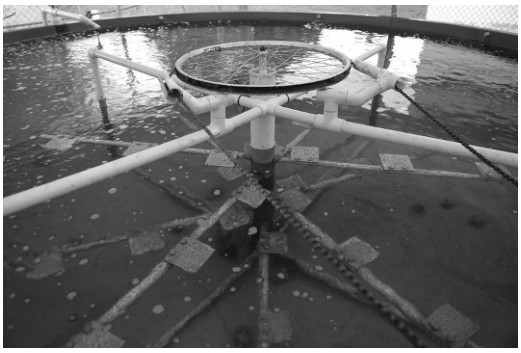

Figure 1: The Coral-sel in position at the UM Aplysia Resource Center. Each attachment site bears experimental plates at positions 15, 50, and 85 cm from the axis of rotation.

Each experimental unit consisted of a ceramic tile (10.8cm x 10.8cm) with limestone blocks (7.6cm x 7.6cm x 0.6cm) secured to its upper (rough) surface. A round (2.5cm diameter x 0.6cm height) plug of live *Montastraea faveolata* was inserted into a matching

hole that had previously been drilled into each square limestone tile (Fig. 2). The plug height was adjusted until it was flush with the surface of the limestone square. Each fragment used in this experiment came from the same parent colony. This colony was relatively flat and had been monitored for over a year in a shallow outdoor tank. Taking all fragments from this single colony maximized the likelihood that variability in responses would be a result of the experimental treatments rather than a result of prior genetic differences, life history, or initial zooxanthellar complement.

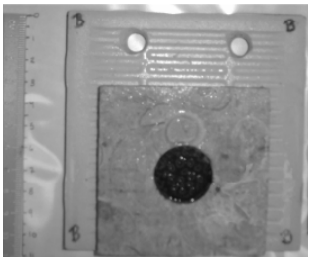

Figure 2: Experimental plate from coral-sel at the initiation of the study. The holes in the ceramic tile allowed attachment to the coral-sel arms with two nylon bolts. The smaller limestone tile is attached using marine sealant. The coral plug sits in a circular hole in the limestone and is attached to the ceramic tile using marine epoxy.

To determine the possible effects of moving the corals in a circular motion compared to passing water linearly over a stationary coral, controls using submersible pumps were tested. Two submersible pumps were each plumbed to allow four nozzles to pump water over stationary coral plates at speeds equal to those experienced by corals 50 cm from the coral-sel's axis of rotation (15.7cm/s). Growth experienced by corals placed in the "pump" treatments could then be compared to that experienced by those in coral-sel treatments.

After construction, and prior to the beginning of experiments, the flow rates at each position were examined using the clod card technique to determine if flow rates at those sites were equal at equivalent positions on the coral-sel (i.e. all 85 cm positions experienced equal flow). This method was also used to verify that the flow rates that the pump platform positions experienced were equal to those experienced by the experimental units in the medium flow treatment on the coral-sel.

All experimental units were removed from the coral-sel bi-weekly. Each was cleaned using a small brush to remove any sediment and algae that had accumulated on the tile. Care was taken when removing material close to the coral in order to minimize the possibility of damaging new coral growth.

After cleaning, excess water was removed from the experimental units using paper towels. The corals themselves were lightly "dabbed" dry, but no pressure was applied. This was to avoid inflicting damage on the delicate coral and skeleton.

Each plate was then weighed on an electronic top loading balance. The weight of each original unit (minus the coral) was subtracted from the measured weight in order to determine the true weight of the fragment at the time of weighing. Weights of coral fragments under different flow conditions were compared statistically using ANOVA.

Each experimental unit, along with a standard metric ruler, and color standard was then photographed using a digital camera. Each photograph was analyzed using the Image J computer program. Using the program, the perimeter of each fragment's surface was traced, and the surface area calculated. The surface areas of fragments were compared statistically using ANOVA.

Results

The experiment ran for a total of 18 months, but three months was adequate to observe significant differences in growth rates based on flow rate (Fig. 3). These preliminary findings showed that flow rate caused significant differences in surface area growth ($p=0.0051$). The lowest flow speed yielded the greatest increase in surface area and the highest flow speed yielded the lowest. The change in area exhibited by the "control" corals placed in front of the pumps, did not vary significantly from that of the corals placed under an equivalent flow rate on the coral-sel ($p= 0.5757$).

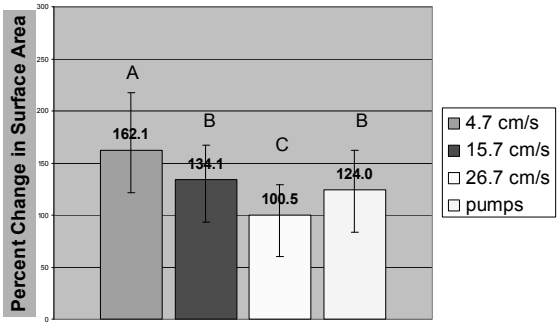

Figure 3: Average percent change in surface area of fragments after sixteen weeks (9/5/2005 – 12/26/2005) . Groups labeled with the same capital letter are not significantly different. ($p = 0.5757$).

Corals experiencing 15.7cm/s of flow showed the highest weight gain over the same period (Fig. 4). Therefore, under these conditions, weight gain was not necessarily dependent on increase in area. In fact, during these early weeks of the experiments when weight increases were standardized to increases in area, the greatest weight/unit area increase was seen

in the high flow speed treatments, though this pattern was altered later in the study.

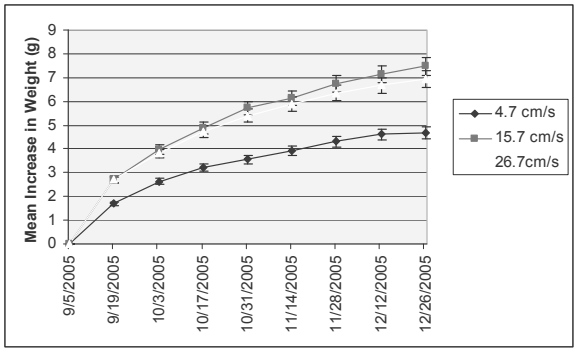

Figure 4: Mean cumulative weight gain over a sixteen week period.

In order to determine whether the water flow rate over a coral fragment influenced the photosynthetic abilities of the zooxanthellae, the electron transtport rates of the zooxanthellae contained in each fragment were calculated using the light curve program of a Walz Diving PAM fluorometer. The fluorometer produced a series of light pulses of increasing intensity, and the fluorescence of the zooxanthellae in response to each pulse was measured and recorded. These values were used to calculate response curves similar to those seen in Fig. 5. Measurements were taken in the morning hours (approximately 0800 to 0930 local time). The ETR curves produced using this method were similar to those seen in figure 5. In general, the maximum electron transport rates of corals on the coral-sel were seen in fragments experiencing the highest flow rates. Under the experimental conditions, the P_{max} level appears to be directly related to the flow rate.

Further examination of the light curves for all fragments reveals that the minimum saturating irradiance for zooxanthellae in these fragments show the same inverse relationship to water flow rate.

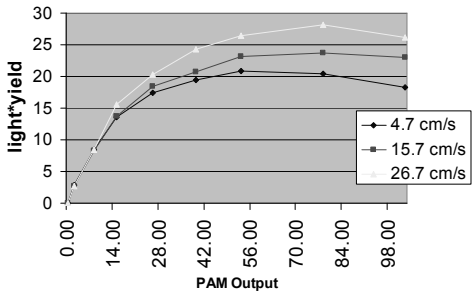

Figure 5: P-I curves exhibited by corals as a function of flow rate.

Discussion

The movement of water over a coral colony can influence its growth and survival through effects on boundary layer thickness. The boundary layer in turn influences polyp movement and prey capture ability (Sebens *et al.* 1998), gas, nutrient, and waste exchange rates, as well as products used in metabolic activities (Kuffner 2001). In addition, flow has been seen to influence the accumulation of mycosporine like amino acids (MAAs) within coral tissues (Jokiel et al. 1997, Kuffner 2001).

While flow has been shown to influence each of the above factors, previous methods of studying flow effects both in the field and in flume systems were unable to completely isolate flow rate itself as an experimental variable. In flume studies, corals experiencing different water flow rates are placed in complete isolation from one another, and water being used to create the flow rates does not mix. This may lead to additional differences in the treatments that vary due to flow, such as temperature and oxygen levels. In the field, corals in areas with different flow rates may also experience different nutrient and food availability conditions.

These confounding factors have made flow as an experimental variable exceedingly difficult to isolate for examination. The solution to this difficulty explored in this study was the "coral-sel method" which allowed fragments of coral to be placed in a common fluid environment, yet still experience different flow rates. The finding that growth on the coral-sel did not vary significantly from growth by corals under similar flow rate conditions in a stationary position add validity to this process as a method to investigate water flow influences on coral.

The coral-sel method allowed water flow effects to be examined with confidence that all other factors, including temperature, light availability, oxygen levels etc. remained equal for corals in all flow treatments. Examination of the corals on a biweekly basis allowed monitoring of changes in coral fragment surface area, weight, and photosynthetic ability. Upon completion of the study, the fragments can be examined to determine whether they have experienced a change in zooxanthellar complement through use of genetic methods. In addition, the fragments can be examined to determine if basic corallite structure changed based on water flow rate alone.

Acknowledgements

I first thank Rob Carter who helped in the original design and construction of the coral-sel prototype. I would like to thank my academic advisor Peter Glynn for his support and advice. In addition, I thank Chris Langdon, Andrew Baker, Daniel DiResta, Robert van Woesik, and Su Sponaugle for their guidance and recommendations throughout the design and experimental phase of

this study. Assistance from the staff of the University of Miami's Aplysia Resource Center, particularly Tom Capo, Albert Boyd, Dustin Stommes, and Phil Gillette, was invaluable during this investigation. Thanks to Andrew Baker for use of the PAM fluorometer. Financial support was received from the University of Miami's Maytag Fellowship, the United States Achievement Academy, and the National Science Foundation.

ASTER bathymetry in computational fluid dynamic simulation of Rongelap Atoll hydrodynamics, Marshall Islands

E.L. Peterson[1,2]

1) School of Engineering and Science, Victoria University, PO Box 14428 Melbourne 8001 Australia
2) Institute for Sustainability and Innovation, Victoria University, Melbourne, Australia

Abstract. ASTER green, red and near infra-red (NIR) imagery with a resolution on the order of handheld GPS echo soundings was calibrated to model bathymetry of Rongelap Atoll to a depth of 10 meters. The ASTER model was converted into of depth contours at 1, 2, 4, 8, and 16 meters. Beyond that depth nautical charts and echo soundings were used to model bathymetry. The combined result was a bathymetric digital elevation model of Rongelap Atoll and surrounding seas, which was converted to X,Y,Z file and for input into reverse engineering software. The reverse engineering software then created a NURBS (Non-Uniform Rational B-Spline) surface model, for input into the finite element meshing program GAMBIT (ANSYS Fluid Dynamics International). These data were then ordered in volumetric and substrate surface elements of coral reefs and input to the FLUENT computational fluid dynamics (CFD) package. Bluelink (Australian Bureau of Meteorology and CSIRO) was used to apply boundary conditions, and results are hydrodynamic charts of the atoll. The resulting map of substrate shear stress at Rongelap is displayed in Figure 2. Figure 2 Benthic shear stress of Rongelap Atoll.

Key words: Atoll, Hydrodynamics, Remote Sensing.

Introduction

Peterson, et al. (2005) argued that computational fluid dynamics are needed to classify regions of benthic shear stress in coral reef ecosystems. That study also presented correlated biological and physical observations from Rongelap Atoll to demonstrate the importance of benthic shear stress in defining habitat suitability in coral reef ecosystems.

The present paper seeks to map Rongelap's previously uncharted waters and to improve our understanding of hydrodynamics in, through, and around the vicinity of this atoll.

Four different datasets were fused to create the digital elevation model employed in the present paper with the ultimate goal to simulate the hydrodynamics of Rongelap Atoll. A nautical chart (Fig. 1) was available, which was copied from Japanese Navy surveys 1917 and 1922 under League of Nations Mandate, and since reprinted by the US government. This chart only covers a fraction of the atoll, and the coordinates of this chart are not WGS84. Likely the original surveys were based on sextant placement of a granite monument (with Japanese characters) found in the main settlement of Rongelap. To this day numerous digital charting products have misplaced every single feature of Rongelap Atoll by at least a mile, but Reston (2007) used the ASTER scene to adjust the chart with WGS84 graticule marks.

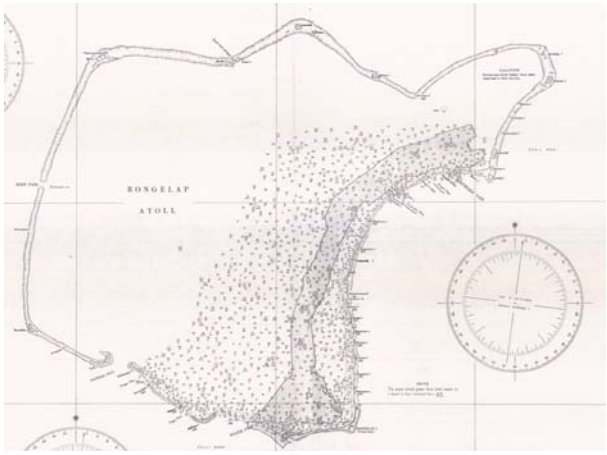

Figure 1: Latest published chart of Rongelap (evidently a copy of Japanese surveys 1917 and 1922, Alele Public Library, Majuro).

Another bathymetric dataset available were coincident GPS tracklogs and echo-sounding during reef surveys (Pinca et al. 2002; Peterson et al. 2005). This largely filled in the western side of Rongelap lagoon, but failed to reach the far northeast corner.

The deepwater bathymetric dataset used in the present study was from Hein et al. (2007). But parts of Rongelap were not covered by the digital elevation model, and little information exists on shallow waters that flood over reef crests. Reefs are by their nature too shallow for navigation, and so not fathomed on nautical charts. Thus, remote sensing is a useful tool to estimate depth. We used an ASTER scene, of which we excluded the blue (B) band, but included the green (G), red (R) and near infrared (NIR) for determination of the land/water interface.

Bathymetric modelling utilises a variety of techniques comparing green and blue wavelengths (Reston 2007). For the present study, visible green only was used for bathymetric calculation, and as a consequence, was expected to yield results with lesser depth penetration than those expected with the inclusion of visible blue data.

Reston (2007) constructed a linear regression model using sub-samples of validation data derived from GPS tracked echo soundings (Pinca, et al. 2002, and Peterson 2005), and historic nautical charts to predict depth from the calibrated ASTER data. Land and breaking water was identified using the NIR band, and assigned a threshold value of 0.5m to preclude their inclusion in the bathymetric calculation, while bathymetry deeper than 20m was assigned that value as a constant. Depth penetration of green light in the ASTER Rongelap scene is approximately 20 metres, exceeding expectations, owing to the clarity and optical penetrative characteristics of the Marshall Islands waters.

An example of results from the southeast corner of the ASTER scene is detailed in Figures 1 and 2, being the main island of Rongelap.

Approximately 15% cloud coverage exists in the NE quadrant of the ASTER image. These have been masked by manually editing contours extracted from the pseudocolour water depth DEM

Material and Methods (CFD modelling)

The ASTER-derived contours of shallow water bathymetry were then kriged together with the nautical chart soundings, NRAS survey track logs and the deep water regional bathymetry to produce a continuous DEM seafloor surface of the Rongelap Atoll region as an ASCII Raster file with 300 meter resolution, and then converted into x,y,z point-cloud data in comma separated values (CSV). The seafloor DEM as CSV was then converted into NURBS (Non-Uniform Rational B-Spline, with algorithms of Bézier & de Cateljau (Farin 2002) surface using ProEngineer "reverse engineering" toolbox (Fig. 4).

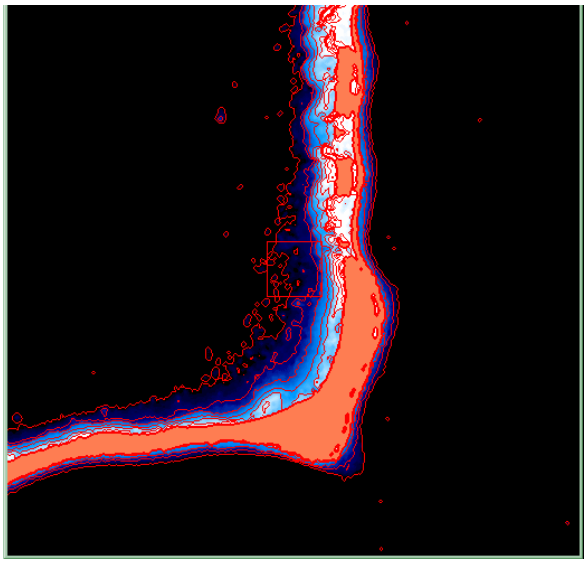

Figure 2: False colour water depth overlain by 0, 2, 4, 6, 8, 10, 12, 14, 16, 18, and 20 m contours in SE corner of Rongelap Atoll.

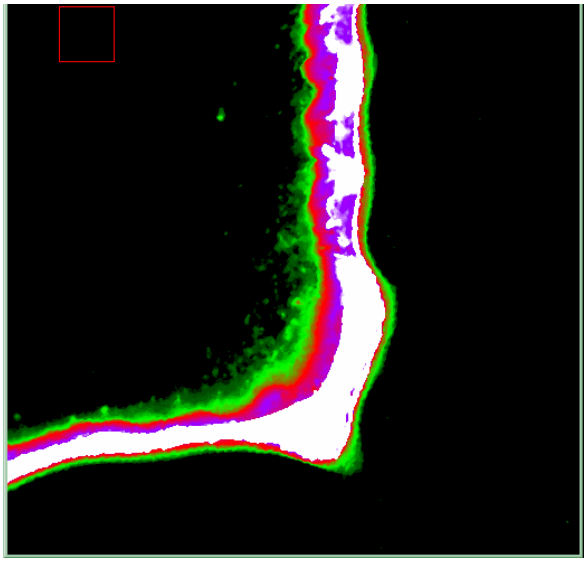

Figure 3: Pseudocolour water depth DEM product in SE corner.

The NURBS surface represents the complex seascape of coral reefs bounding the lower face of the fluid flow problem, while the upper surface is given a fixed-lid approximation as determined by sea level as the air/water interface. This modelling approach suits extensive submergent reefs such as Micronesia with only "small islands" set in trade wind circulated seas. The NURBS surface was saved in IGES format and then imported into the meshing program GAMBIT (Figure 5) for development of the CFD domain.

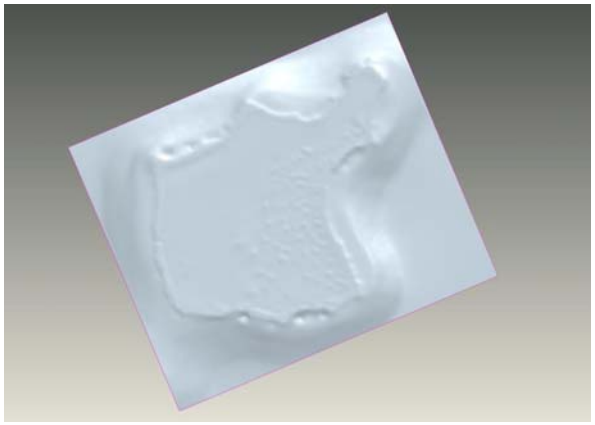

Figure 4: Screenshot from ProEngineer of Rongelap NURBS.

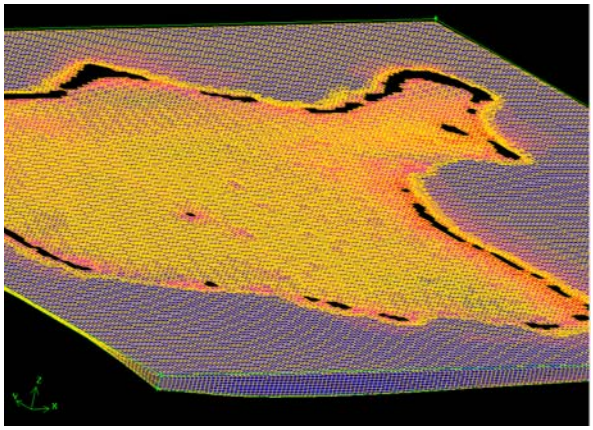

Figure 5: Screenshot from GAMBIT mesh generation for Rongelap model. Slicing ten meters into the domain, islands and reef flats appear as voids, but there is flow allowed to go over all areas.

The computation mesh was then read into Fluent software with the imposition of boundary conditions referencing the BLUELink conditions of Figure 6:

- Sea surface – wall allowed to slip with specified wind shear 10 knot (5 m/s) tradewind driven current flow east>west stress vector (1,0,0) [Pa]
- Sea floor – no-slip wall and with shear stress reactions evaluated by CFD
- Sea to north, south, and west – Current from east (-.2,0,0) [m/s] velocities from BLUELink (www.bom.gov.au).
- Sea to west – low pressure exhaust [-100Pa].
- turbulent intensity ~30% of mean flow based on BLUELink> 1st-14th Jan 2000.
- hydraulic radius ~ 1000m depth of ocean.

BLUELink> is described by Brassington (2007).

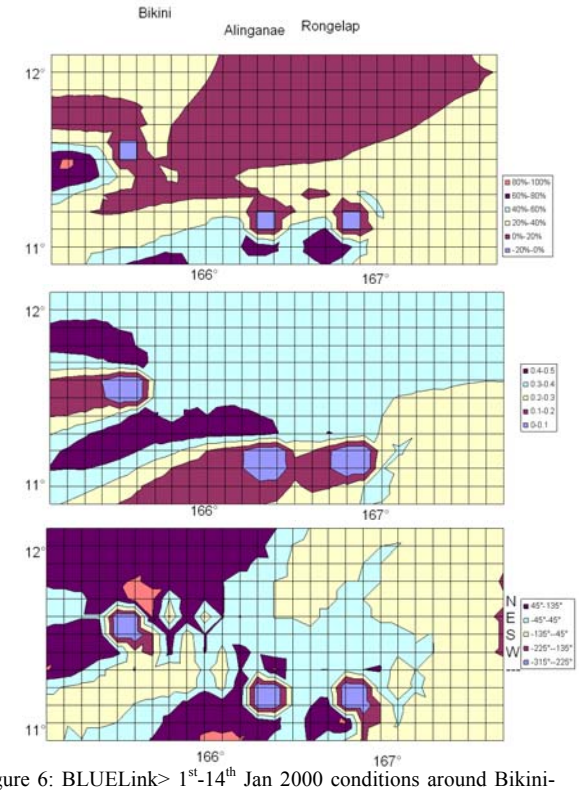

Figure 6: BLUELink> 1st-14th Jan 2000 conditions around Bikini-Alinganae-Rongelap region. Turbulent Intensity above, mean speed middle, and direction below.

The turbulent viscosity model is realizable k-epsilon with the following features:

- Turbulent intensity $I = u'/\bar{U}$ = rms/speed
- Eddy scale ~ 7% of hydraulic diameter
- Turbulent kinetic energy $k = {}^{3}/_{2}\cdot(\text{speed}\cdot I)^2$
- Turbulent dissipation rate $\varepsilon = 2.35\ k^{3}/_{2}/L$
- Turbulent viscosity $\mu_t = 0.09\ \rho\ k^2/\varepsilon$

Results

Preliminary benthic shear stress results of simulation are illustrated in Fig. 7. The strong red spot on the main island of Rongelap is fictional, since this island is not actually covered by the present sea level. This result could be masked out with polygons of land, to provide a Geographical Information System product of the CFD simulation.

Other important products of the CFD model could be the larval connectivity matrix between each reef, but this has not yet been produced for Rongelap Atoll.

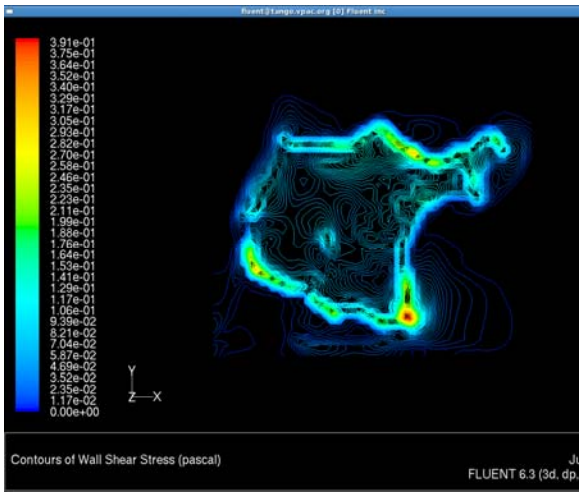

Figure 7: Resulting benthic reaction [Pa].

Discussion

BLUELink> provides real-time 11km resolution hydrodynamic conditions throughout the Indo-Pacific. This provides an opportunity to model local areas of interest, such as Rongelap Atoll. BLUELink> provides seaward and airside boundary conditions to CFD modelers. It is then a problem of nesting mesoscale models within the regional model provided by BLUELink.

Convergence has generally improved in solutions where u,v,w components of flow are specifically mapped at the seaward boundaries of the CFD model. It has proven better to also define the western seaward boundary with explicit velocity components rather than an exhaust condition.

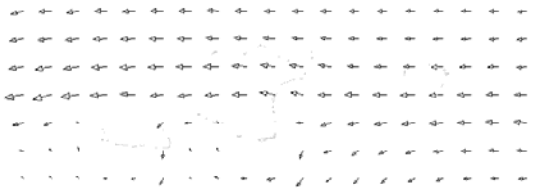

Figure 8: BLUELink> surface vectors around Alinganae and Rongelap Atolls 1st January 2000. Many layers of the ocean, and many years of daily data are available by automated web queries.

The DEM will be extended around Rongelap to match the BLUELink grid illustrated in Figure 8. The DEM model of Hein et al. (2007) extends well into these deeper waters, and so it will not be difficult to resample it to produce a larger NURBS domain. For hydrodynamic modeling of the Rongelap region, the hypothesis is that the critical factor to determine flow through atoll systems is the shallowness of the reef flats, where red and green light penetration is amply suited to measure bathymetry. Figure 9 illustrates the thin sheet of fast moving flow over a reef flat.

Figure 9: Flow over Rongelap reef flat, particle tracked with GPS.

The CFD model is yet to be validated with the GPS tracklogs illustrated in Figure 9. In that particular fieldwork exercise a tide guage was set up to establish a staging-curve of flow over the reef flat. An echo-sounder provided the depth of water, while the gps measure the velocity of surface water flow of a snorkler following slightly positively buoyant floater illustrated in Figure 10. Thus each tracklog has a coincident depth log, and so the two integrate volumetric flow over the reef flat per cross unit width.

Figure 10: Flow over reef flat, tracked with echo-sounding GPS

Abstract. In 2004 and 2005, five drowning accidents in Ishigakijima, Okinawa were documented by Japan Coast Guard and were found to be caused by a strong offshore current commonly known as "reef current". This type of current has been identified to be responsible in generating the circulation of water and transportation of sediment in coral reefs. In this paper, however, high-speed offshore current in coral reefs is specifically referred to as "reef rip current". Considering that the generation mechanism of reef rip current is not revealed yet, the researchers conducted a hydrodynamic study in Yoshiwara Coast, Ishigakijima, Okinawa in two phases (normal and storm conditions) during summer season to determine the location and time of occurrence of the strong offshore current that will significantly address safe utilization of coral reef and carbonate beach thereby reducing drowning accidents. The nearshore hydrodynamic project that was undertaken included field measurement of wave, current and tide during normal and storm conditions with the implementation of bathymetry survey by laser method. The results revealed the maximum 20-minute average offshore velocity at 1.2m/s. In addition, it was observed during low tide condition that most of the water inside the lagoon is only discharged through the reef gap.

Key words: Reef rip current, tide and wave dominated, coral reef, safe utilization, water circulation

Introduction

Coastal areas in tropical and subtropical regions are characterized by coral and normal sandy beaches that are attractive for tourists around the world thus making beach and marine tourism one of the fast growing economic industries. On the other hand, utilization of beaches also poses a risk on the safety of the coastal users who are not familiar of nearshore current system. Hence, field study and analysis of drowning accidents in carbonate beach and coral reef have been implemented and conducted in Japan's subtropical region, Okinawa Prefecture particularly in Yoshiwara coast, Ishigakijima in order to establish and describe the strong offshore current mechanism.

Monismith (2007), Kench et al. (2006), Tamura et al (2006), Hearn (2001, 1999), Nadaoka et al. (2001), Yamano et al. (1998), Kraines et al (1998), Symonds et al. (1995), Gourlay (1994), Young (1989), Roberts et al. (1975) among others have studied and made scientific publications on hydrodynamics in coral reefs in tropical and subtropical regions. However, the impact of nearshore current on safe utilization of carbonate beach and coral reef has not been fully established yet. Literatures have revealed that circulation in reef systems is typically driven by a combination of tidal flow, wind-driven flow (Yamano et al. 1998) and flow induced by the breaking of wind-waves on the reef flat (Kraines et al. 1998; Symonds et al. 1995; Hearn and Parker 1988; Nadaoka et al. 2001) and that currents and deepwater waves are significantly modified by reef morphology (Roberts et al. 1975) in a consistent manner dependent on tidal elevation, reef elevation, and reef width (Kench et al. 2006). Currents on the fore-reef shelf exhibit a distinct periodicity near the diurnal tidal frequency wherein the characteristic of the deep (21m) shelf margin is rather unidirectional (Roberts et al. 1975; Kraines et al. 1998) and high-velocity flow (>50cm/s), but on the shallow shelf, a weaker (5-7cm/s) and more

directionally variable currents are found (Roberts et al. 1975). During a typhoon, abrupt decrease and increase of the water temperature with a resultant of about 10C lower than before was documented in the study by Nadaoka et al. (2001). The numerical simulation of Tamura et al. (2006) which showed good agreement with the observed data revealed that currents have an appreciable magnitude of tide-averaged velocities, even during neap tides, which are governed mostly by wave set-up effects.

In this study, however, the relationship and impacts of nearshore hydrodynamics to safe utilization of carbonate beach and coral reef are the key issues.

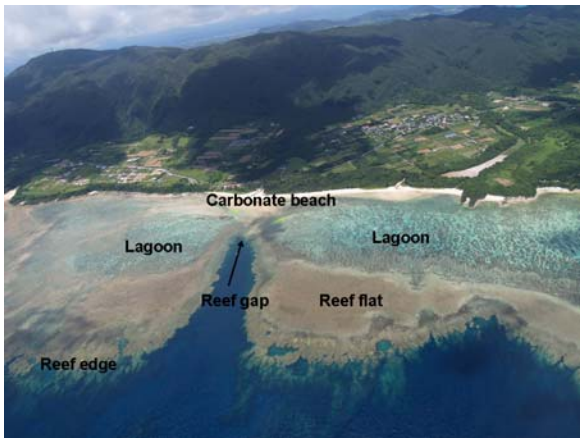

Figure. 1. Aerial view of study site in Yoshiwara Coast

Materials and Methods

A nearshore hydrodynamic project was carried out in Yoshiwara, Ishigakijima's carbonate beach and coral reef coast (Fig. 1) in two phases; Phase 1 was performed during normal condition (small wave and tide dominated) and Phase 2 during storm condition (high wave and tide dominated). The project was implemented in summer season from June 25 to July 25, 2006, the period when the occurrence of drowning accidents had been reported.

An aerial laser survey was conducted for two days by an airborne team from the Sixth Region of Coast Guard in Hiroshima on the actual study site to produce the bathymetry map with high resolution (Fig. 2).

Parameters such as water level, wave height, wave period, water temperature, current and wind speed and direction both in Phase 1 (June 25-July 1, 2006) and Phase 2 (July 1-25, 2006) conditions were obtained through field measurement with the aid of field equipment such as wave gages, electronic current meters (ECM), ADCP, tide gages, thermometer, GPS floats, and anemometer as well as fluorescent dye experiment. These data parameters were analyzed to describe further the wave, tide and current patterns occurring and behaving in coral reef and carbonate beach and consequently to establish their respective relationship.

Results and Discussion

Morphology

The aerial laser survey that produced the bathymetry map in Fig. 2 shows a developed reef flat and lagoon system. The offshore length of the reef system is more than 1,000 meters. Profiles of the reef gap area and the well-developed reef flat and lagoon indicated by transect lines 1 and 2 respectively are shown in Fig. 3. The cross-section along transect line 1 passing thru the reef gap area spans a 250m length of horizontal flat and gradually drops to a depth more than 40m. However, the well-developed cross-section of the reef flat and lagoon indicated by transect line 2 extends a 920m horizontal flat and abruptly drops to a depth more than 40m. Carbonate beach is also developed at the mouth of the river and reef gap boundary. There are also narrow channels that are directed toward the reef gap.

Nearshore wave and current are governed by hard bottom reef geomorphology. In general, incident high wave dissipates its energy over a reef edge and flat depending also on tidal level, i.e., the ratio of waterdepth to wave height. The current in reef lagoon may become weaker but will be faster near the reef gap (locally called "mouth of the coral reef" in Okinawa) which is the location where there is significant geomorphological feature to control the current system inside a reef. Geomorphology of coral reef is the fundamental information to estimate wave and current system, and to justify its safe utilization.

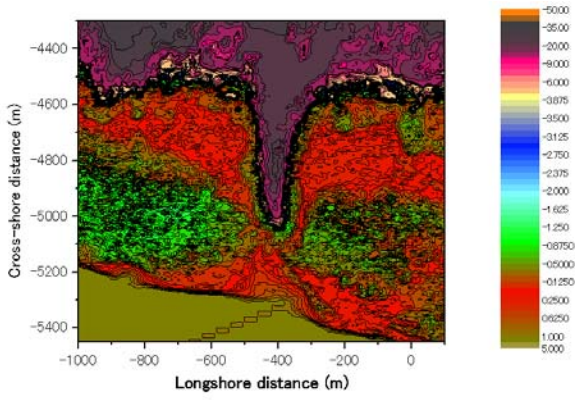

Figure 2. Bathymetry of study area (Yoshiwara coast, Ishigaki, Okinawa Prefecture)

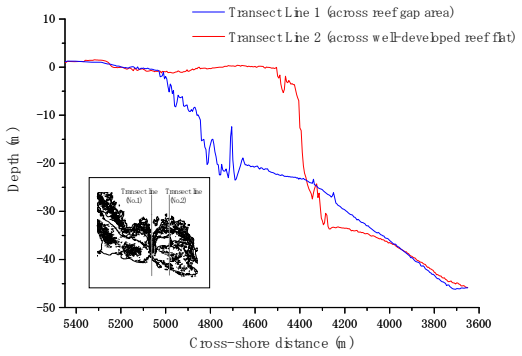

Figure 3. Cross-shore profile of the study area at the reef gap and reef flat (Yoshiwara coast, Ishigaki, Okinawa Prefecture)

Flow visualization by dye and GPS floats

Nearshore current system can be visualized with the aid of dye experiment and GPS floats. Figure 4 shows the point of application of the dye (Pt. A) and its diffusion pattern. The width of the dye is an indication of the strength of the offshore flow which increases in speed as it approaches the reef gap (Pt. B, about 250m in length). As offshore flow moves out from the reef gap, its speed starts to slow down as the flow continues to pass through a much wider cross-sectional area (Pt. C). This is visually represented by the diffusion of the dye which also describes the flow pattern direction.

Figure 5 also shows the flow pattern inside and outside of coral reefs, especially around the reef gap. Small GPS floats originally developed for a study on rip current on sandy beach by Nishi et al. (2003) were applied. The GPS floats are intended to provide direction flows of major and minor currents starting from the points of application from the sandy beach through the reef gap and offshore as represented by Path Lines 1-5 (Fig. 5). Another direction flow mechanism was also applied in conjunction with the GPS floats by a drifter having a GPS gadget that moved in the direction of the current flow (Fig. 5, labeled as staff with GPS) to verify and substantiate flow pattern characteristics and measurements converging through and diverging from the reef gap.

Velocity of a reef rip current

One week duration of nearshore hydrodynamic observation was first conducted from June 25 to July 1, 2006. Figure 6a shows the change in water level inside the lagoon. The tide shows semidiurnal variations. The maximum water level reached up to 2.4m and minimum water level at 0.8m with a tidal difference of 1.6m. The second observation was conducted from July 1-25, 2006 in the presence of storms where maximum and minimum water levels were recorded at 2.5m and 0.75m respectively (Fig. 6b) which resulted into a slightly higher tidal difference at 1.75m.

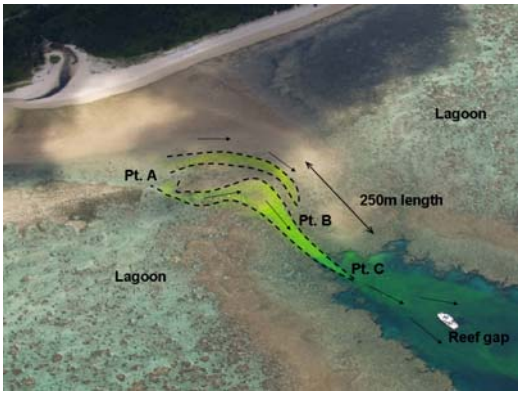

Figure 4. Dye experiment (dye pattern shows an offshore current toward a reef gap)

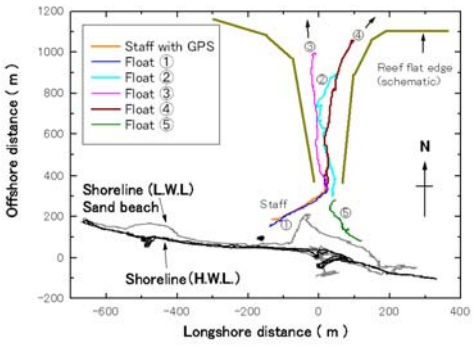

Figure 5. Offshore flow pattern starts from the carbonate beach and moves outside the coral reef through the reef gap

The 20-minute average velocity record in the narrow channel near the reef gap (Fig. 7a) indicates high offshore velocity up to 1.2m/s at ebb tide and reasonably high onshore velocity up to nearly 0.7m/s at flood tide during low tide conditions. The reason for this is attributed to reef edge and reef gap which entrap the water inside the lagoon and outside the reef system respectively. This scenario is similar to a hydraulic dam especially when the water level inside the lagoon becomes lower than the elevation of the crest of the reef flat. At this point, most of the entrapped water inside the lagoon would be concentrated and discharged through a reef gap. Moreover, when the tide changes into flood tide, the crest of the reef flat also has the function to be a barrier against flood tide when the water level is lower than the crest of the reef. Thus, the flood tide (onshore current) is also concentrated into the reef gap. The first and

second peaks of 20-minute average velocity correspond to offshore current and onshore current respectively. Storm condition also forced and triggered the generation of wave height nearly 1.0m at the shoreline. Given this magnitude, it is expected that a much stronger offshore current will yield. However, for safety and precautionary reasons, the equipment had to be relocated to a less risky position which then measured the maximum velocity at 0.25m/s (Fig. 7b). Based on water level and current velocity data, an inverse proportionality relationship has been established as shown in Fig. 8. It is evident that the existence of high-speed current at the reef gap occurs during low tide condition. This scenario has been verified by Japan Coast Guard and local people as to the period when the drowning accidents occurred in Ishigakijima, Okinawa (Nishi et al. 2007).

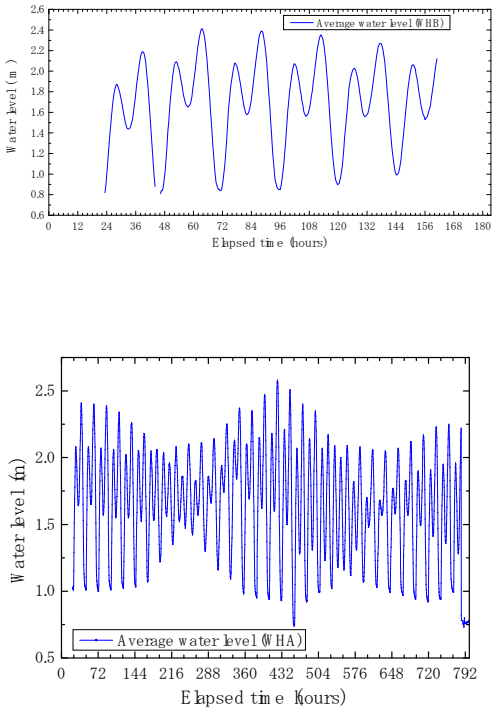

Figure 6. Tide record at the study site (upper panel) normal condition (June 25 – July 1, 2006), (lower panel) storm condition (July 1 – July 25, 2006)

Mean water level

Mean water levels inside and outside of coral reef produce spatial gradients which enhance the flow around a reef gap. To reveal the mechanism of strong offshore and onshore currents through a reef gap, four water level gages were installed on the hard sea bed. The installation points are shown in Fig. 9, one located outside the coral reef at the reef gap, another one on the reef flat near the reef edge, one in the middle of the lagoon, and one in front of the carbonate beach. The water level was measured every 1 second and expected to measure and run up to 11 days. However, due to some mechanical problems, data were stored for the first 36 hours during the first fieldwork. Superposition of four mean water level data is shown in Fig. 10.

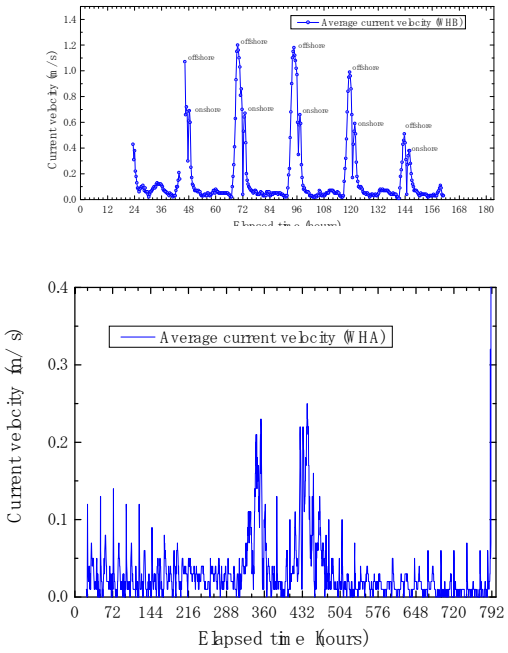

Figure 7. 20-minute mean velocity record (upper panel) normal condition (June 25 – July 1, 2006) (lower panel) storm condition (July 1 – July 25, 2006)

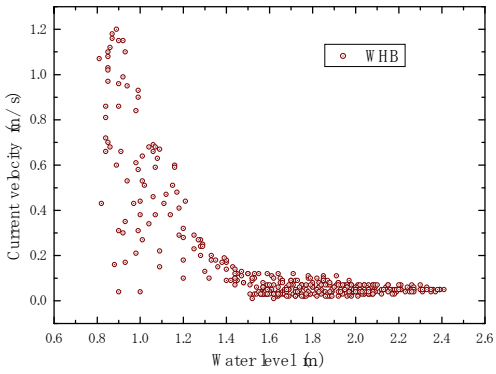

Figure 8. Relationship between current velocity and water level

Furthermore, it has been established that the spatial difference in mean water level is indeed significant especially during the lowest low tide. From the

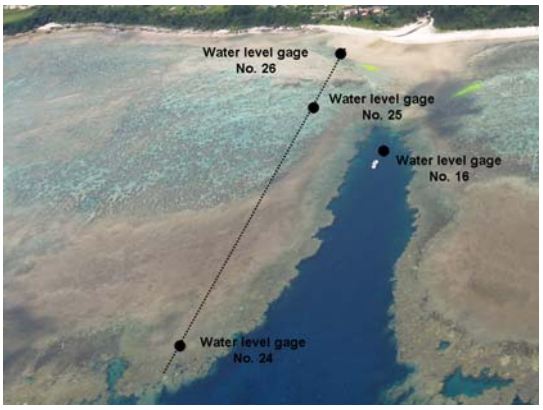

Figure 9. Orientation of water level gages (Gage 16 at the reef gap, Gage 26 on the carbonate beach, Gage 25 in the reef lagoon, and Gage 24 on the reef edge)

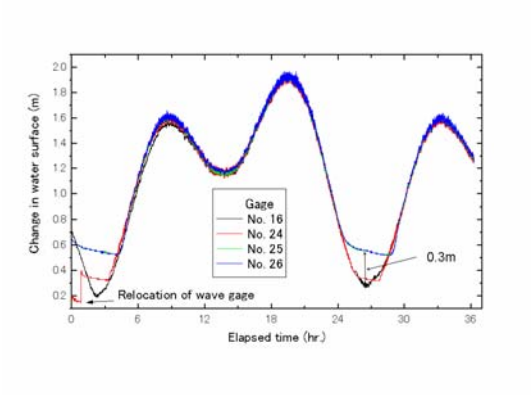

Figure 10. Mean water level outside of coral reef (No.16), on reef edge (No. 24), in the middle of lagoon (No.25), in front of carbonate beach (No.26)

field measurement, it was revealed that the mean water level inside a coral reef was higher than the mean water level outside of coral reef by as much as 0.3m (Fig. 10). Translating this gradient in terms of velocity expressed by $v = \sqrt{2gh}$, where g represents gravitational acceleration and h is the difference in water head, results into a rough estimation of 2.4m/s that is in fact twice as much as that from the observed data. This clearly shows that a spatial gradient of 0.3m would generate a strong current by more than 1m/s at the reef gap which is considered to be an upper limit of coastal users' (swimmers, etc) workability in water specifically in Japan.

Conclusion

The nearshore hydrodynamic study described the reef rip current phenomenon generated by tide and wave has revealed the following;

(1) During low tide conditions, the maximum 20-minute average velocity was measured as much as 1.2m/s even though the significant wave height is small (0.12m).

(2) The reef gap has a function to control exchange of water mass inside the coral reef especially during low tide. The reef flat works as a boundary to entrap the water in the lagoon and allows it to be discharged through the reef gap at low tide.

(3) A resultant spatial gradient in the mean water level inside and outside of coral reef is one of the most important mechanisms of the existence of a strong reef rip current.

Using cellular diagnostics to link land-based sources of pollution with coral reef degradation in South Florida

P. Dustan[1], J.E. Fauth[1] , E. Pante[1], K. Banks[3], B. Vargas-Angel[4,] C.A. Downs[5]

Abstract. Linkages between land-based sources of pollution and coral reef health were assessed at ecological, physiological and cellular levels at four paired inshore and offshore stations off Broward County, Florida, U.S.A.: a biomonitoring control site, a treated wastewater outfall, an inlet mouth, and a treated wastewater outfall adjacent to an inlet mouth. Live coral cover was <4% at all sites and most inshore sites clustered together because they had less bare substrate and considerable cyanobacteria (*Lyngbya* sp.). Cellular diagnostics revealed that the stony coral *Porites astreoides* at all sites was stressed compared to colonies from a more remote Bahamian site. Offshore corals exhibited higher biomarker accumulations than inshore colonies. Corals near ocean outfalls and from protected areas in the Florida Keys had diagnostic profiles consistent with treated wastewater exposure. Profiles of offshore colonies were consistent with xenobiotic detoxification. Corals regenerated from sampling lesions at the two offshore biomonitoring control sites and two other inshore sites. Regeneration rates at offshore sites near the offshore ocean outfall and shipping channel were negative. Congruence between ecological, physiological and molecular information demonstrates that using multiple bioindicators can identify linkages between land-based sources of pollution and distressed coral reefs.

Key words: biomarkers, *Porites astreoides*, coral reef health, treated wastewater

Introduction

Land-based sources of pollution are critical factors influencing the fate of coral reefs off the heavily populated southeast Florida coast. Here, we describe a project that integrates traditional monitoring methods with new bioindicator technology – cellular diagnostics – to address how treated wastewater discharge and shipping channels affect coral reefs.

Cellular diagnostics was designed to assess the condition of reef-building corals and identify mechanisms of coral pathologies (Downs 2005 and references therein). It works because environmental stressors affect organisms by overwhelming defenses at lower levels of the biological hierarchy: molecular, cellular, and organismal-level homeostatic processes. By evaluating coral responses at these and higher levels of the biological hierarchy, scientists can provide resource managers with critical information needed to identify and ameliorate stressors before an ecosystem-scale crisis occurs (Fauth et al. 2003)

Methods

Sampling occurred at four paired, inshore and offshore stations located near a treated wastewater outfall, an inlet mouth, a treated wastewater outfall located within an inlet mouth, and a biomonitoring control site off Broward Country, Florida, USA (Table 1). The mustard hill coral (*Porites astreoides* Lamarck) was chosen as the focal species because it is distributed across the shelf in south Florida and is amenable to cellular-diagnostic analyses.

Cellular Diagnostics

Diagnostic antibodies included assays for oxidative stress (copper-zinc superoxide dismutase [Cu/Zn SOD] and ferrochelatase [FC]), cellular metabolic condition (glucose-regulated protein [GRP 75] and total small heat shock proteins [sHsp]), protein metabolic condition (ubiquitin and heat shock protein 60 [Hsp 60], indicators of xenobiotic response (cytochrome P450-2 class [CYP 2], cytochrome P450-6 class [CYP 6], cnidarian glutathione-S-transferase [GST] and multi-drug resistance protein [MDR]). Details are provided in Fauth et al. (2006).

Corals were sampled with a 1.5cm punch, placed in opaque canisters underwater, blotted dry on deck, frozen on dry ice, and stored at -80° C. Frozen samples were ground to a powder, proteins extracted

in buffer, repeatedly centrifuged to generate a soluble protein (TSP) and assayed according to methods described in Downs (2005).

Table 1. Sampling sites (see Banks et al 2007 for precise location)

Coral Colony Health

Health of coral colonies was assessed by quantifying the rate at which hole-punch lesions healed (Fisher et al. 2007). Five colonies at each site were sampled in January, 2005, and re-measured 8 mos later. Lesion area was calculated as an ellipse, and regeneration rate expressed as $mm^2\ d^{-1}$. We also estimated percent old and recent tissue loss using Atlantic and Gulf Reef Rapid Assessment (AGRRA) protocols (Kramer et al. 2005).

Ecosystem Assessment

Digital video 15-25 m transects were used to estimate percent cover. Video was converted to single-frame for pointcounting (15 pts./frame) to estimate percent projected cover of uncolonized (bare) substrate, stony corals and other functional groups: gorgonians, zooanthids, porifera, macroalgae, and the cyanobacteria *Lyngbya* (Dustan et al. 1999).

Statistical Analyses

Multivariate analysis of variance tested the null hypothesis that reef location (inshore versus offshore), and proximity to treated wastewater outfalls and shipping channels (diagnostic responses transformed as $\log_{10}(x + 1)$ had no effect on coral responses . Separate univariate tests interpreted significant MANOVA results and Tukey's Honestly Significant Difference separated univariate means. Hierarchical clustering revealed patterns in coral diversity, bottom cover and cellular-diagnostic responses. All analyses used JMP V. 4.0.4 (SAS Institute, Inc., Cary, NC, USA) at $\alpha = 0.05$.

Results

Community Composition

Sites clustered into two groups. Three inshore sites (FTL1, PE2 and HWO2) had the lowest substrate cover, highest *Lyngbya* , and least cover by sponges, stony corals and soft corals. All four offshore sites plus the inshore HI2 site clustered together because they had the highest percentages of bare substrate, the lowest cover of *Lyngbya*, and the most cover by sponges, stony corals and soft corals. (Fig. 1).

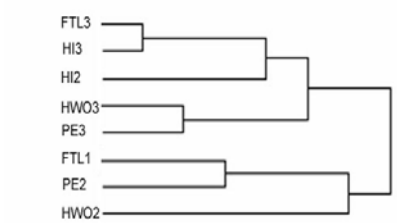

Fig 1. Sites clustered by community composition as percentage cover of functional groups described in text.

Cellular-Diagnostic Responses

Significant variation in the vector of ten cellular-diagnostic responses was explained by depth ($P < 0.001$), proximity to ocean outfalls ($P < 0.003$), depth x shipping channel ($P < 0.04$) and ocean outfall x shipping channel ($P < 0.02$). Eight parameters contributed most to the significant multivariate response: Hsp 60, Grp 75, ubiquitin, CYP 2, CYP 6, FC, MDR and GST. Accumulations of sHsp and Cu/Zn SOD did not vary with depth or proximity to potential land-based sources of pollution (Fig. 2).

Offshore corals, averaged across all sites, had significantly more Hsp 60 (protein metabolic condition) than did inshore corals ($P < 0.006$). Colonies from HI, a site near both a treated wastewater outfall and shipping channel, had less Hsp 60 than expected (significant interaction term: ANOVA $F_{1,29} = 10.57$, $P < 0.003$). Ubiquitin levels varied with the depth x shipping channel interaction ($P < 0.043$). Corals at inshore sites without a nearby shipping channel had twice as much ubiquitin as colonies at inshore sites with a shipping channel nearby. In contrast, corals at offshore sites had intermediate ubiquitin levels (Fig. 2)..

Grp 75 levels varied with the ocean outfall x shipping channel interaction ($P < 0.001$). Averaged across both depths, corals at HWO had more than three times as much Grp 75 as colonies at the biomonitoring and HI sites. FC levels varied significantly with the depth x ocean outfall interaction ($P < 0.03$). Corals at inshore sites near ocean outfalls had less FC than colonies at inshore sites without an ocean outfall and offshore sites with an ocean outfall nearby. Offshore colonies at sites without an ocean

outfall were indistinguishable statistically from these two groups (Fig. 2).

CYP 2 and GST levels were both higher offshore ($P < 0.02$). Averaged across depths, sites without shipping channels had CYP 6 levels 26% higher than sites with shipping channels ($P = 0.045$). Mean MDR levels varied with depth, ocean outfall, and the ocean outfall x shipping channel interaction (all $P < 0.034$). On average, mean MDR levels were 26% lower inshore compared to offshore sites, and 30% lower near ocean outfalls compared to those without them. In addition, mean MDR levels were significantly higher at the FTL biomonitoring sites than at the two HWO sites. Mean MDR levels at the paired PE and HI sites were statistically indistinguishable from both of these groups (Fig. 2).

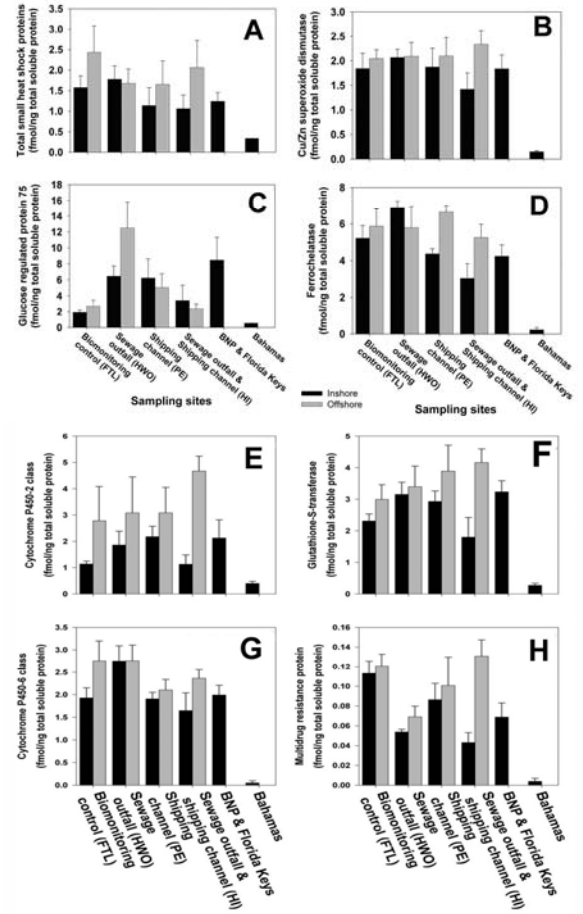

Fig. 2 Mean (± SE) accumulation levels for small heat shock proteins (A), Cu/Zn superoxide dismutase (B), glucose regulated protein 75 (C), ferrochelatase (D), Cytochrome P450-2 (E), glutathione-S-transferase (F), Cytochrome P450-6 class (G),multidrug resistance protein (H).

Coral Lesion Healing

Lesion regeneration rate varied significantly with depth and the sewage outfall x shipping channel interaction (Table 5). Coral colonies at all inshore sites except PE had lesion regeneration rates

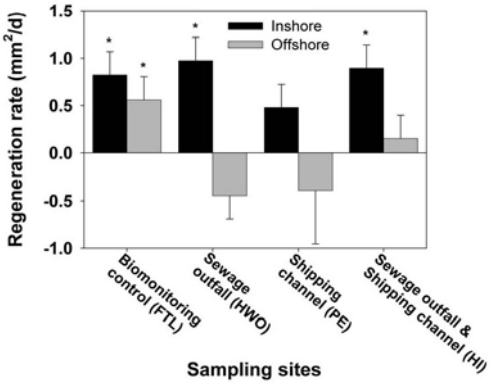

Fig 3. Regeneration rates (mm^2/d) of mustard hill corals (*Porites astreoides*). Data are least squares means (± 1 SE) from analysis of covariance, with initial lesion size as the covariate. Asterisks signify regeneration rates that differed significantly from zero. N = 1-5 colonies at each location.

significantly greater than zero (Fig. 3). In contrast, among the offshore sites only colonies at the biomonitoring control site had regeneration rates significantly greater than zero. Rates at the three other offshore sites were indistinguishable statistically from zero; mean regeneration rates at the offshore sewage outfall (HWO3) and shipping channel (PE3) were negative (Fig. 3).

Correlated Responses

Developing prognostic indicators of coral condition requires linking parameters of molecular and cellular function with the fitness of individuals and ecosystem structure and function (Depledge et al. 1993, Moore 2001, Fauth et al. 2003, Downs et al. 2005). In *Porites astreoides* sampled off Broward County, percent tissue loss regressed positively on GRP 75 accumulation (regression equation: Log_{10}(% mortality + 1) = 0.48 + 0.042[GRP 75 + 1]; hereinafter, concentrations in fmol/ng total soluble protein; $P < 0.008$, $R^2 = 0.20$), which is essential for cell proliferation. Backward stepwise selection identified a log-log model with Grp 75, ubiquitin, CYP 2 and CYP 6 as predictors of percent tissue loss. Coral colonies with low ubiquitin levels and high levels of Grp 75, CYP 2, and especially CYP 6 lost the most tissue (regression equation: Log_{10}(% mortality + 1) = $1.32 + 0.042\log_{10}$[GRP 75 + 1] - $0.84\log_{10}$[ubiquitin + 1] + $064\log_{10}$[CYP 2 + 1] + $2.15\log_{10}$[CYP 6 + 1]; $P < 0.005$, $R^2 = 0.40$). Similarly, levels of ubiquitin, CYP 2 and CYP 6 were significant predictors of lesion regeneration rate (regression equation: Log_{10}(% mortality + 1) = $-0.091 + 1.03\log_{10}$[ubiquitin + 1] – $1.32\log_{10}$[CYP 2 + 1] - $3.14\log_{10}$[CYP 6 + 1]; $P < 0.005$, $R^2 = 0.40$). Coral colonies with high ubiquitin levels and low levels of CYP 2 and CYP 6 possessed highest regeneration rates (Figure 4).

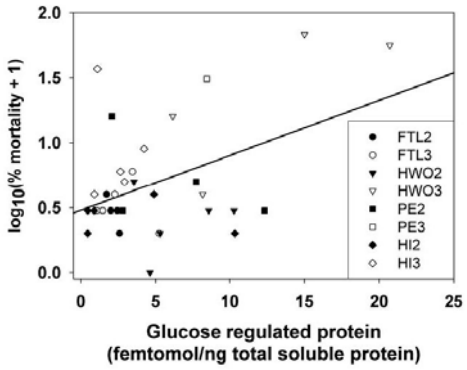

Fig 4. Log-linear regression of coral tissue mortality (%) as a function of glucose regulated protein (mortalin). Regression equation: Log 10 (mortality +1) = 0.48 + 0.042 Grp 75 (femtomoles/ng soluable protein). $F_{1,32}$= 8.10, P<0.008, R^2 = 0.20.

Comparisons with other Geographical Locations

Accumulations of every cellular-diagnostic parameter at the eight Broward County sites were indistinguishable from *P. astreoides* sampled the same month in Biscayne National Park and the Florida Keys. However, all biomarkers at every U.S. site were higher than those of *P. astreoides* from offshore Little Exuma Island, the Bahamas (two colonies, located approx. 23°30 N, 75°23W). The only exception was Hsp 60, which was undetectable in Bahamian corals and not differ from zero in inshore HI colonies. Cluster analysis (see Fauth et al. 2006) confirmed these analyses and the two Hollywood outfall sites (HWO2 and HWO3) clustered with FKNMS (Florida Keys National Marine Sanctuary) corals; the remaining inshore and offshore sites formed natural groups.

Discussion

Coral responses at the cellular, individual, and community levels provide a comprehensive assessment of the potential effects of land-based sources of pollution. Considered together, they suggest that corals off the southeastern Florida coast are exposed to poor-quality water, which reduces the ability of colonies to repair small lesions such as those created by our biopsy punches or by herbivores such as parrotfishes. In turn, this may reduce the ability of corals to colonize, grow and reproduce, thereby contributing to the low coral cover typical of this area (Banks et al. 2007). A study conducted further south in the Florida Reef Tract (Fisher et al. 2007) drew similar conclusions, which suggests this pattern may be widespread and common.

In our study, cellular diagnostic parameters indicative of xenobiotic stress were elevated at all our stations and in Biscayne National Park and Florida Keys National Marine Sanctuary, compared to corals in the Bahamas. This broad pattern illustrates the need to include a control distant from major sources of anthropogenic stress. *Porites astreoides* from the Bahamas had very low levels of all cellular-diagnostic parameters, and total sHsp was below detection limits there. High levels of cnidarian sHsp at all eight Broward County stations indicate they were responding to an oxidative stress (Downs et al. 2006).

The two stations near the Hollywood treated wastewater outfall and in the FKNMS possessed high levels of GRP 75, or mortalin. This enzyme is induced by glucose deprivation and involved cellular senescence and transformation. Elevated GRP 75 levels were associated with increased amounts of coral tissue loss. Colonies at these sites also had high levels of ubiquitin, which tags damaged proteins for degradation. Combined, these results suggest treated wastewater alters coral nutrition by generating higher than normal protein turnover rates , which inhibits coral growth and recruitment and results in decreased coral cover (Pastorak and Bilyard 1985, LaPointe et al. 2004).

Elevated levels of Hsp 60, CYP 2 and MDR at offshore sites FTL3, PE3 and HI3 are consistent with oxidative damage caused by exposure to xenobiotics. Cytochrome P450-2 class is induced by electrophilic carcinogens, drugs, and other environmental pollutants, which it oxidizes in a cellular suicide reaction. Glutathione-S-transferase conjugates the oxidized xenobiotic to glutathione, which is then pumped from the cell by multidrug resistance protein thus lowering the intracellular concentration of toxic compounds below their level of toxicity (Bard 2000). Increases in MDR usually occur only in response to an organic xenobiotic (Bard 2000; Sauna et al. 2001). The antibody used in this study binds both the cnidarian and dinoflagellate isoforms, hence results are a composite of MDR expression in both. Together, these results are consistent with offshore corals at the FTL3 biomonitoring site and off Port Everglades and Hillsborough Inlet reacting to exposure to anthropogenic contaminants. Regeneration of sampling lesions was negatively correlated with elevated levels of CYP 2, which suggests that mounting xenobiotic defenses had a metabolic cost: impaired ability to repair tissue damage.

Coral colonies at three inshore stations (FTL1, PE2 and HI2) and Biscayne National Park were characterized by cellular-diagnostic responses that tended to be lower than at the other Broward County sites. Corals at these three inshore stations also had moderate to high regeneration rates and little tissue loss, which is consistent with the defense trade-off hypothesis. While seemingly contrary to conventional wisdom, nearshore patch reefs in the

Florida Keys lost less live coral cover than more offshore reef communities (Porter et al. 2001). On such inshore reefs, coral colonies appear to be in better condition than conspecifics at offshore reefs, in part because inshore colonies accumulate defensive compounds more rapidly and return to homeostasis quickly once stressors recede (e.g., Downs et al. 1999; Fauth 2004; Downs et al. 2005). Inshore habitats are intrinsically more variable and much of the difference between inshore and offshore corals may have an ecotypic basis.

Total tissue loss was greatest near the City of Hollywood's treated wastewater outfall and moderately high at the offshore Port Everglades and Hillsborough Inlet stations. These three stations also had lesion regeneration rates indistinguishable from zero, and in two cases (HWO3 and PE3) tended to be negative; lesions grew larger instead of healing. Inability to regenerate small lesions indicates that conditions were poor for coral growth and reproduction at these sites between January and August, 2005.

Greatly elevated levels of cellular-diagnostic parameters and low coral cover at all sites we sampled off Broward County are cause for concern, especially because regeneration rates were indistinguishable from zero at four of eight stations. Our study establishes a line of evidence suggesting that land-based sources of pollution negatively affected the status and trends of these coral reef communities, which therefore should receive greater protection from potential damage caused by these stressors.

Acknowledgements

Many thanks are due to the captain and crew of the R/V Thomas L. Sullivan, E. Hodel and A. Renegar, and V. Paul. Biomarker antibodies and calibrant standards were gifts from R. Richmond, University of Hawai'i, in turn gifts from EnVirtue Biotechnologies, Inc.. This study was permitted by the Florida Fish and Wildlife Conservation Commission (SAL #04SRP-846 and 04SR-830), Biscayne National Park (Permit #BISC-2004-SCI-0031), and National Ocean Service Permit FKNMS-2004-022. This project and the preparation of this report was funded in part by a Coastal Zone Management Administration grant from the United States Department of Commerce through an agreement/contract with the Office of Coastal and Aquatic Managed Areas, of the Florida Department of Environmental Protection. The total cost of the project was $52,746, of which $52,746 or 100% was provided by the United States Department of Commerce.

Area-Calibrated Automation of Coral Classification for Near And Subsurface Reef Videos

Ma.S.A.C. Marcos[1], L.T. David[2], M.N. Soriano[1]

1) National Institute of Physics, University of the Philippines, Diliman, Quezon City, 1101 Philippines
2) Marine Science Institute, University of the Philippines, Diliman, Quezon City, 1101 Philippines

Abstract. Groundwork for an area-calibrated computer-automated system for benthic classification through underwater video is presented. Data acquisition through an underwater video camera is fast, less expensive and processing can be done in one day. Two video acquisition schemes were considered: (1) near-reef videos, where height of 30 cm from the reef surface is maintained, and (2) subsurface video of a reef where the camera is fixed 0.2-0.5m below the surface. Rapid classification is implemented via downsampling a reef image into blocks. Benthic components are classified into living and nonliving categories. For near-reef videos, an overall success rate of 79% is achieved even for corals occurring in various morphologies. Color and texture features derived from video stills were used as inputs to the classifier system. For subsurface reef video, an overall recognition rate of 60 – 70% was achieved. A more accurate percent cover is obtained via an area calibration model developed. This model is based on camera optics and removes the need for an underwater reference object for area correction. The development of an automated rapid reef classification system is most promising for reef studies that need fast and frequent data acquisition of percent cover of living and nonliving components.

Key words: coral classification, reef monitoring, automation, computer vision, pattern recognition

Introduction

The general approach to coral reef monitoring is determining population of benthic organisms or components in a reef such as living coral, dead coral, algae and sand, rock or rubble (Kenchington and Hudson 1984). Data on percent cover of different benthic components in a reef also helps in assessing damages or degradation on the reef incurred by trawling, storm or anthropogenic factors. A framework for an automated coral reef classification system from underwater video captured from near-reef and subsurface locations is presented. The goal is to automatically identify benthic components and to output an accurate percent cover with appropriate area calibration. An automated classification system is applicable for fast and frequent monitoring of reef organisms for temporal observations which can be correlated at once with specific occurrences, e.g. storm, dynamite fishing, etc. Investigation towards reef community studies can also be done using the system.

The science of determining benthic population data depends on the scale needed for assessment. For reef areas needing a resolution of at least 25 m^2, the commonly-used methods for monitoring are multi-spectral satellite imagery and aerial remote sensing (Mumby et al. 2004). Results from this method however need on-site validation. A limitation as well is the monetary cost of one remotely-sensed image. The method introduced in this study is a rapid, low-cost technique for on-site benthic cover estimation.

To estimate benthos distribution on site, several protocols have been put in practice such as manta tow, and Line-Intercept Transect (LIT) (Kenchington and Hudson 1984) which is an application of SCUBA. Recent monitoring methods such as Video Point Sampling (Uychiaco et al. 1992; Carleton and Done 1995) employ image and video capture in LIT to reduce diving time by allowing the counting to be done in the lab through playback. At playback, random points are generated on the screen and distribution is estimated by identifying and counting the objects directly underneath the points. Software such as *Coral Point Count with Excel* (Kohler and Gill 2006) has been developed for determining coral and substrate coverage using advanced methods in image processing. However, the method uses random point count sampling, which still requires user intervention and expertise in identifying the benthic components underneath overlaid points on the video frames. The aforementioned methods are quite taxing and take weeks to complete data collection for a reef span of only a kilometer. The tediousness of analysis and the long duration of time for acquisition and processing are not practical for marine management studies that require rapid observation of the effect of ecological disturbances on a reef that can occur in a matter of days.

The first published research on benthic component classification using computer vision techniques were applied to conventional LIT video and subsurface video (Marcos et al. 2005; Marcos et al. 2007). These papers introduced good classification for near-reef and subsurface video. In this study, area calibration is applied to benthic classification for underwater video using simple mathematical derivations from camera optics. This provides a more accurate benthic percent cover that accounts for changing camera-reef distances especially for subsurface videos. Area calibration removes the need for submerged reference objects for area estimation. The applicability of the automated system on new reef areas with a comparison on the results from a five-point sampling method is also presented in this paper.

Color and texture are utilized as cues to assign unique numerical identifiers for benthic categories. Color features are reliable indicators because it has minimum if not negligible variability across image scales and illumination. Also, there is good separability in color feature space for living and dead corals which are predominantly chromatic and achromatic, respectively. Texture features are utilized to distinguish living benthos, often occurring in regular and smooth textures, from sand and rubble substrates that generally have irregular textures. The combination of color and texture features can distinguish dead corals and dead coral with algae categories.

Material and Methods

Near-reef videos are acquired through LIT method via video capture done at approximately 30 cm from the reef surface. Underwater videos of coral reef transects from Talibon, Bohol (FISH Project, Marine Science Institute, UP Diliman) are utilized. Classification categories are living (live coral and algae) and nonliving components (dead coral, sand and rubble). 625 sub-images are employed for the training and the test set (living: 240; nonliving: 385). Selection of these sets is based on clarity and vividness of contrast and color. Alive corals are generally colorful and regularly textured while nonliving components are achromatic. Ground truth is provided by the Marine Science Institute of UP Diliman.

The subsurface reef videos are acquired in Ngedarrak reef, Republic of Palau. A Sony Model 2020IR bullet-type underwater submersible camera and an echo sounder are lowered on a motor-powered boat about 0.2-0.5 m from the water level. Boat speed is maintained at around 2 knots. The echo sounder was attached beside the video camera to simultaneously estimate the depth. Video acquisition was done on April 14, 2006.

Raw image sizes of 480×720 pixels were reduced to half (240×360 pixels) for fast computation. Percent cover from reef video is obtained by "downsampling" (Marcos et al. 2007) the video frame into small blocks (30×30 pixels), and each block is classified whether it is living or nonliving. Doing this for all blocks in a video of a reef area vis a vis per pixel classification provides a fast measure of living and nonliving benthos distribution. Prior analysis of the effect of varying block sizes and video frame interval sampling have found that recognition rates do not differ by more than ± 5-6%.

Fig. 1 illustrates video acquisition of the camera throughout the reef topology. Because the reef has variable height, the field of view varies with changing camera-reef distances (e.g. regions 1 and 2 in the figure). When counting the distribution of a benthos type, it will have more block counts for the shallower depth (region 1) than in greater depths (region 2) for a fixed actual benthos size/area. It is then more appropriate to estimate physical area distribution rather than using point-intercept method in reporting benthic distribution especially for subsurface video. For the system to obtain accurate and reliable percent count of any benthos, area calibration is needed.

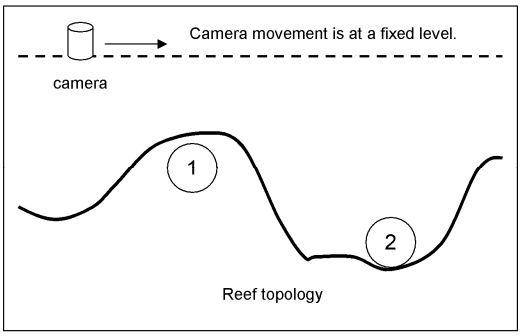

Figure 1: Illustration of video acquisition at different heights of the reef topology. Percent cover counting should be corrected for varying field of view due to changing distance between camera and reef.

For pinhole imaging as shown in Fig. 2, the field of view angle of an imaging system varies with object distance by the following equation:

$$\alpha = 2\tan^{-1}\left(\frac{I_V}{2x_I}\right) \quad (1)$$

where x_I is the lens to imager distance and I_V is the vertical measurement of the camera's imager. From the camera optics of Figure 2.6 combined with the thin lens equation: $1/x_O + 1/x_I = 1/f$, where x_O is the lens to object distance and f is the focal length, the actual vertical and horizontal field of view equation for a CCTV camera is derived as:

$$H = I_H\left(\frac{x_O}{f}\right); \qquad V = I_V\left(\frac{x_O}{f}\right) \quad (2)$$

where I_H and I_V are the horizontal and vertical sizes of the CCD imager of the camera, respectively. For underwater video capture, imaging variation due to the index of refraction of sea water is accounted through Snell's law where seawater decreases the field of view by 33%. Hence by multiplying I_H, I_V, $1/f^2$ and 0.33 a calibration factor C can be obtained for any submersible CCTV camera:

$$FOV_{horiz} \times FOV_{vert} = 0.33 \frac{I_H I_v}{f^2} x_0^{\,2} = C x_0^{\,2} \quad (3)$$

A calibration factor of $C = 0.44$ was found for the camera setup used in this study. This means that area calibration can be done when there is numerical data on camera specifications and camera-reef distance (obtained through echo sounder). Thus a submerged reference object is no longer required.

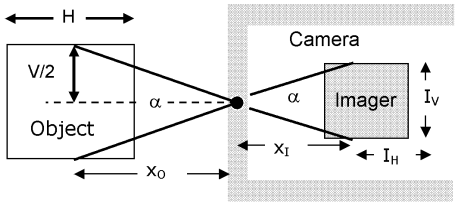

Figure 2: Basic optics of a CCTV camera

Color and Texture Features

The color features in (Marcos et al. 2005), the normalized *r-g* color space, are used which was found to be the best color feature among several color spaces tested for benthic classification. The color feature is computed from the RGB pixel values of the raw image frames from video.

A texture feature is a numerical description of intensity patterns (or patterns of pixels or group of pixels) in an image area. The rotation-invariant Local Binary Pattern histogram (Ojala et al. 2002) is utilized because it was proven to perform well on rotated, tilted and illumination-varied three-dimensional textures (Maenpaa et al. 2004). It was also shown to be a suitable texture descriptor for benthic components (Marcos, et al., 2005).

Classifier

Linear Discriminant Analysis (LDA) which is based on Bayesian theory is used as classifier. LDA is simple to calculate from data and is reasonably robust, i.e. the results are good even when the classes do not have normal distributions (Kuncheva 2004). Using the classification criterion to minimize total error of classification (TEC), the classifier will attempt to make the proportion of object that it misclassifies as small as possible. LDA employs Bayes Rule to assign an object to the group with highest conditional probability. All probabilities are assumed to have a multivariate normal distribution and all groups have the same covariance matrix C. An x_k is assigned to group i with the maximum value of

$$f_i = \mu_i C^{-1} x_k^T - \tfrac{1}{2} \mu_i C^{-1} \mu_i^T + \ln(p_i) \quad (5)$$

where μ_i is the mean of group i and p_i is equal to total sample of each group divided by the total samples.

Ground Truth

Expert-analyzed ground truth data was used to verify the output benthic cover of the system. To facilitate a fast point-by-point analysis (Fig. 3) a Matlab-based Graphical User Interface coral reef ground truth system (GUI-Coral Truth) was developed. The GUI-Coral Truth allows all sections of an image to be classified into five categories: coral, dead coral, dead coral with algae, sand and rubble for depths of 1 to 8 meters. Due to poor visibility at depths of more than 6 meters, ground truth error from visual inspection of the videos is expected to be large.

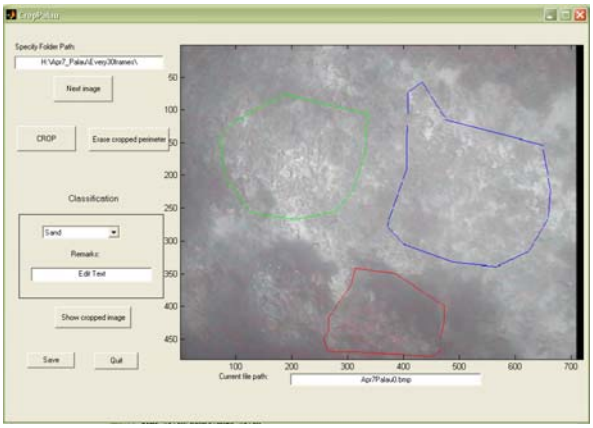

Figure 3: Graphical User Interface (GUI) developed for ground truth establishment

Results and Discussion

Near-reef Video

Table 1 shows the result of classification for the Bohol reef images where 79% recognition rate is obtained. This result verifies the potential of the classification system for identifying coral reef components from video of different reef areas.

Benthic cover result from a training set obtained from the same test site (Bohol reef) is compared with the result from a training set of a foreign/different site (Table 1). A non-zero trace with zero off-diagonal elements indicates a perfect (100%) recognition rate in a confusion matrix. The difference in percent cover count for foreign vs. same site training set reveals site-specificity in choosing the training set for classification. This is expected mainly because of different water quality conditions for both sites, which affects the signal-to-noise ratio of images acquired. Fig. 4 show visual comparison of this result Most

regions in the image are misclassified when a foreign training set is used. It is recommended then that training images for a specific reef area be taken from reef images of the same site.

Overall Recognition Rate			79%

Subsurface Video

The subsurface benthic classifier achieved a high success rate in identifying living components especially at shallower depths, reaching a high 85% recognition rate at 3-meter depths. 75% recognition rate was obtained for nonliving components. Incorrect classification is attributed to occurrences of non-achromatic rubble images due to shadows cast by their structures and/or algae growing on them. A decline in success rate was observed with increasing camera-reef distances, as expected with the decrease in visibility . The automation was accomplished in approximately two hours using Matlab software and a computer with a Pentium 4 processor (1.5 GHz) and 1 GB memory.

Percent Cover with Area Calibration

To validate the area calibration in eq. 3, real-world area of field of view obtained from image measurements was plotted against various camera-object (resolution target) distances as shown in Figure 5. A quadratic fit of $y = 0.442x_O^2 + 0.512x_O$ was computed, where y is the area of field of view and x_O is the object distance from the camera. This is in good agreement with the derived calibration factor (Eq. 3) of $0.44x_O^2$. The second term in the quadratic fit is attributed to nonlinear factors inherent to the camera optics and the water column (refractive index of sea water may not be constant or equal to 1.33). It is also ascribed to skewing of the camera during video capture.

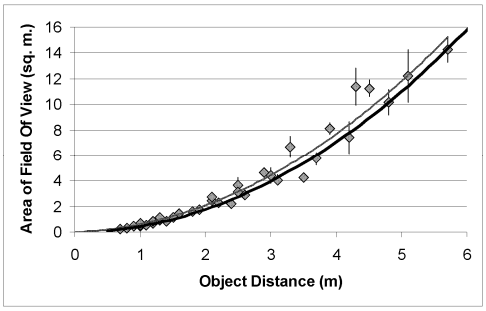

Figure 5: Validation of the area calibration factor. Data points represent actual field of view area measured directly from the images and processed via equation 12. The light trend line denotes a quadratic fit of $y = 0.442x_O^2 + 0.512x_O$ ($R^2 = 0.96$), where y is the area of field of view and x_O is the object distance from the camera. The field of view calibration factor we derived in equation 3 ($y = 0.44x_O^2$) is represented by the bold line.

The actual spatial area cover of living and nonliving components of subsurface reef video captured from the Ngedarrak Reef, Palau was computed after area calibration. Depths greater than 6 meters produce video frames that lack visual clarity and thus were excluded because of a large uncertainty in ground truth establishment through video inspection. Cumulative area cover of living and nonliving components was computed at increments of 1 meter camera-reef distance (Table 2). This will determine the maximum depth to acquire subsurface video where accuracy of percent area cover may fall below acceptable values. It is emphasized though that acceptability of any experimental result is dependent on the end user. From Table 2, it can be surmised that for a user requiring a spatial cover accuracy of more than 70%, the classification system can be applied to videos acquired up to depths of 2 meters. It is emphasized that identification of coral reefs only at depths of 2 meters is already immensely useful for marine scientists especially when analyzing results of

environmental catastrophes such as typhoons which affects shallow reefs in general.

Table 2: Comparison of cumulative derived area of living and nonliving components from classification system and from ground truth. The success rate based from ground truth area are indicated.

Camera -reef distance	Area derived from classification (m2)		Area derived from ground truth (m2)		% Success Rate
	Living	Nonliving	Living	Nonliving	
1 to 2 m	0.73	0.38	0.93	0.18	75.70
1 to 3 m	6.65	3.35	6.54	3.46	56.20
1 to 4 m	14.52	7.83	12.60	9.75	46.90
1 to 5 m	22.18	15.13	19.17	18.15	46.10
1 to 6 m	26.19	17.30	24.65	18.85	48.00

Comparison of Method with Video Point Sampling

The system developed in this study for subsurface video analysis of reef video is compared with video point sampling using five points as markers. The point sampling classification was done by Mr. Victor Ticzon of the Marine Science Institute, UP Diliman. Subsurface video was sampled from 9 stations along the Lingayen gulf, Pangasinan.

Comparison of computed hard coral cover from both methods are illustrated in Fig. 6. For the automated classification, training images were obtained from the site itself. Nine of 11 stations analyzed by both methods have less than 10% difference in percent cover estimates of live coral cover. Small difference in these results reveals that both methods can gain similar or comparable results. It is emphasized though that frames that lack visual clarity are removed from the analysis in both methods. Although fixed point sampling is the standard method used by most marine scientists in determining percent cover, the classification system introduced in this paper exploits all information from the image, i.e. every region in the image is considered.

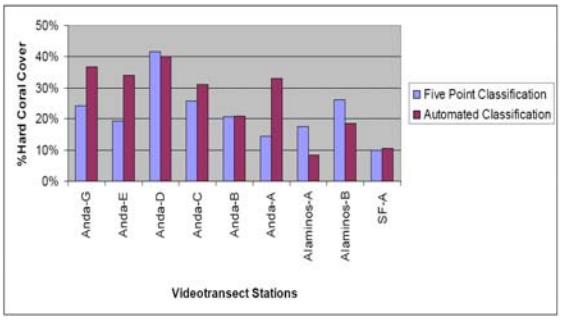

Figure 6: Bar graph of the percent cover of hard corals in 9 stations of the Lingayen gulf as assessed by five point classification and the automated classification developed.

This study on classification for near and subsurface reef videos provides groundwork for developing rapid automated systems for benthic classification and mapping using a simple reef transect video. Area calibration is introduced since point-intercept method is inadequate in reporting percent cover due to variability in camera-reef distances. This calibration model also eliminates the need for submerged reference objects. Although this study, which is the first to explore automation of subsurface benthic images, have obtained a fair accuracy rate in classifying living benthos, it is highly likely that improved image quality from better camera optics and electronics can yield higher recognition rates even at greater depths.

The applicability of the system's current performance would depend on the field study objectives and the needed accuracy. If rapid assessment of coral cover is desired especially in reef areas affected by typhoon and oil spill, then the system would suffice as long as video is taken at 2 meter depths. Although video point sampling protocol is the current standard in determining benthic cover because of its high recognition accuracy, this process is quite tedious and needs expert manning. Nonetheless, our system can be used to supplement results from multi-spectral imagery, and even video point sampling.

Large scale coral mortality in Barbados: a delayed response to the 2005 bleaching episode

H.A. Oxenford[1], R. Roach[2] and A. Brathwaite[2]

2) Coastal Zone Management Unit, Ministry of Family, Youth, Sports and Environment, Barbados.

Abstract. Corals in Barbados suffered widespread bleaching during the high temperature event of 2005. Six reefs were monitored for one year (October 2005 – November 2006) to determine mortality impacts and rate of recovery from this bleaching event. Five 1 x 20 m band transects and five 20 m line transects were quantitatively surveyed at each site, every four months. Bleaching prevalence dropped from a mean of 71% of colonies in October 2005 to 38% in February, to 17% in June, before rising again to 25% in November 2006. Coral mortality remained low for five months (means: 3.8% colony surface dead; or 4.8% dead cover), but rose sharply after 10 months (means: 18.7% colony surface; or 25.9% cover), eventually declining after 15 months to near ambient levels (means: 2.0% colony surface; or 6.1% cover). Like other eastern Caribbean islands, recovery from bleached condition was slow and overall mortality impact was high on both deep and shallow reefs. In contrast were the delayed onset of mortality and low incidence of coral disease. High losses in live coral cover have significant economic implications for the island which derives a major proportion of its GDP from tourism, and relies heavily on healthy reefs for coastal protection.

Key words: coral bleaching, mortality, Barbados.

Introduction

Coral reefs across the Caribbean suffered extensive bleaching as a result of the record high temperature event of 2005 (Donner et al. 2007; Souter and Wilkinson 2008). In particular, the eastern Caribbean Lesser Antilles experienced unprecedented heating stress, and high levels of coral mortality were reported for several islands by early 2006 (Miller and Muller 2006; Bouchon et al. 2008; Morgan et al. 2008; Woody et al. 2008).

In Barbados, bleaching impact was very high, but the initial mortality response was low compared with early reports from other eastern Caribbean islands (Oxenford et al. 2008). Here we examine the cumulative mortality impact of the bleaching episode on Barbados reefs over the ensuing year.

Methods

Quantitative surveys were conducted at three shallow (<10 m) and three deep (>15 m) reef habitats along the west and southwest coasts of Barbados (see Oxenford et al. 2008 for reef study site locations and descriptions) every four months from September/October 2005 to November 2006. At each reef site, five haphazardly placed 1 x 20 m belt transects and five rapid assessment 20 m line intercept transects were surveyed.

Extent of bleaching was assessed along the belt transects by recording the number and species of all coral colonies and the number suffering partial or full bleaching. This was presented as transect mean percent colonies bleached for each reef site.

Coral mortality was assessed using two independent indices: 1) visually estimated percent of each colony surface recently dead (recorded for every colony encountered in the belt transects by species), and 2) percent of benthic coral cover recently dead (measured directly along the entire length of the line intercept transects without regard to species identification). Recently dead coral was identified by the presence of newly exposed white skeleton with or without a fine layer of green turf algae (see Lang and Marks 2006). This 'state' was observed to last only a matter of weeks in tagged corals before reverting to 'old' mortality (Oxenford, unpubl. data). Therefore, cumulative mortality (calculated as the sum of recent mortality recorded each survey) was used to represent the full mortality impact of the bleaching event. Mortality data were presented as transect means per site for both indices.

Species complexes *Montastrea* (*M. annularis, M. faveolata, M. franksi*) and *Agaricia* (*A. agaricites, A. humilis, A. lamarcki, A. grahamae*) whose individual species could not be reliably identified by all observers, were treated as single species (*Monastrea* spp. complex and *Agaricia* spp. complex respectively) in the analyses.

Benthic water temperatures were recorded *in situ* at

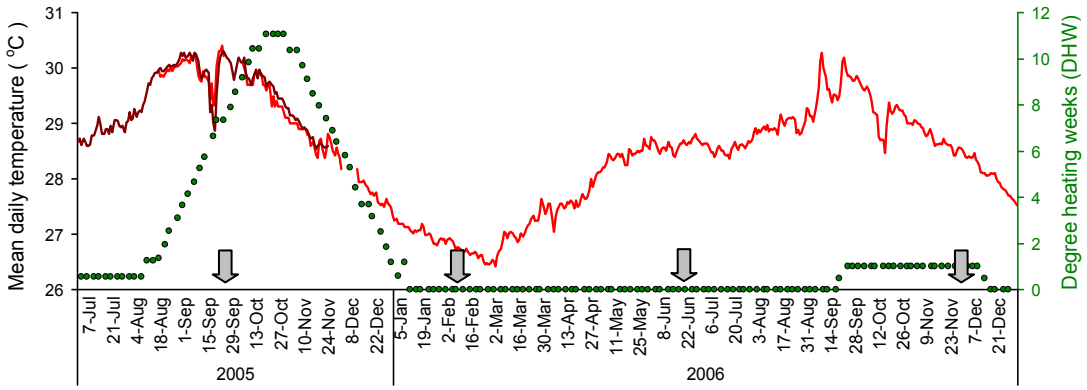

Figure 1. Benthic water temperatures recorded at two reef sites in Barbados, shown together with NOAA/NESDIS computed degree heating week data for the island. Dates of coral surveys are indicated by filled arrows.

deep and shallow sites every 4 h using HOBO® Water Temp Pro data loggers fixed in the reef. Computed mesoscale (50 km grid) degree heating week (DHW) data (Liu et al. 2006) were accessed from the archived NOAA/NESDIS Coral Reef Watch database at http://coralreefwatch.noaa.gov/satellite/hdf/index.html.

Results

The benthic water temperature and DHW time-series experienced by Barbados corals during late 2005 through 2006 are shown in Fig.1. In 2005 benthic water temperatures had exceeded 29.5 °C by the first week in August 2005 at both deep and shallow sites and persisted for almost three months. By comparison, in 2006 benthic water temperatures rose to 29.5 °C by the first week in September, but lasted for less than one month (Fig. 1). Heating stress was first apparent in Barbados in late May 2005, with values of 0.55 DHW persisting from May 24 - August 9. Heating stress rose sharply thereafter, reaching record highs of 11.05 DHW in the second half of October, and persisted through early January, 2006 (Fig. 1). The summer of 2006 was cooler with relatively low heating stress (1 DHW) occurring from late September to early December.

Bleaching was severe from late 2005 into 2006, affecting both shallow and deep reef habitats, virtually all hard coral taxa and the majority of colonies (see Oxenford et al. 2008), and persisted over the full year of study (Table 1). Bleaching prevalence gradually declined from a high of 70.6% of all colonies across all reefs in late September/early October 2005 to 17.1% in June 2006, 10 months after the initial onset of bleaching. Prevalence then rose again to 25.3% in November 2006 after summer warming (Table 1, Fig. 1).

Shallow reefs suffered significantly higher levels of bleaching than deeper reefs initially (Mann-Whitney: $U = 18$, $n = 30$, $P < 0.001$), showed no statistically significant differences in February or June ($U > 69$, $n = 30$, $P > 0.200$ in both cases), but by November the situation had reversed, with deep reefs suffering on average significantly more bleaching than shallow reefs ($U = 55$, $n = 30$, $P = 0.017$; Fig 2).

Table 1: Summary of bleaching prevalence of surveyed reefs shown as mean percent of all colonies that were fully or partially bleached along five 1x20 m belt transects at each reef site. SE in parentheses.

Reef site		Survey Dates							
		Oct-05		Feb-06		Jun-06		Nov-06

All reefs mean		70.6	(2.6)	37.5	(2.5)	17.1	(2.0)	25.3	(2.8)

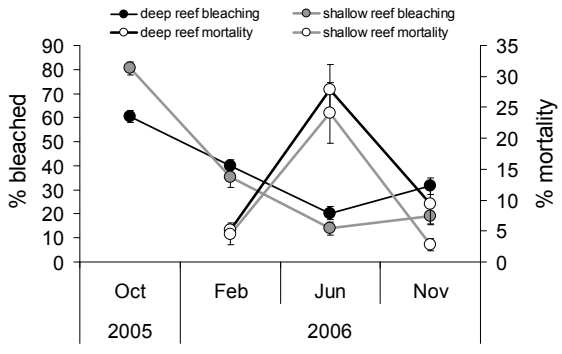

Figure 2. Mean bleaching and mortality responses of corals on deep and shallow reefs in Barbados to the 2005 hot water event. Bleaching is shown as mean % of coral colonies affected; mortality is shown as mean % of recently-dead benthic coral cover; bars show standard error.

The two coral mortality indices were highly correlated (R^2 = 0.904, n = 36), showing the same patterns among reef sites and the same trend over time (Fig. 3). However, the belt transect method, measuring whole coral colony surface, consistently estimated slightly lower mortality values than the rapid assessment, line intercept method measuring benthic coral cover (Fig. 3).

Bleaching-induced mortality, when first examined in February 2006, was relatively low across all reefs (mean % colony surface recently dead: 3.8% ±0.1 SE; mean % benthic coral cover recently dead: 4.8% ±1.0 SE), but rose sharply after 10 months (June 2006 – mean colony surface: 18.5% ±2.5 SE; mean cover: 25.9% ±3.2 SE), eventually declining after 15 months to near ambient levels (November 2006 - mean colony surface:2.0% ±0.4 SE; mean cover: 6.1% ±1.8 SE). Cumulative mortality impacts of the bleaching event are therefore estimated at approximately 24.3% loss in live coral colony surface or 36.8% loss of live coral benthic cover.

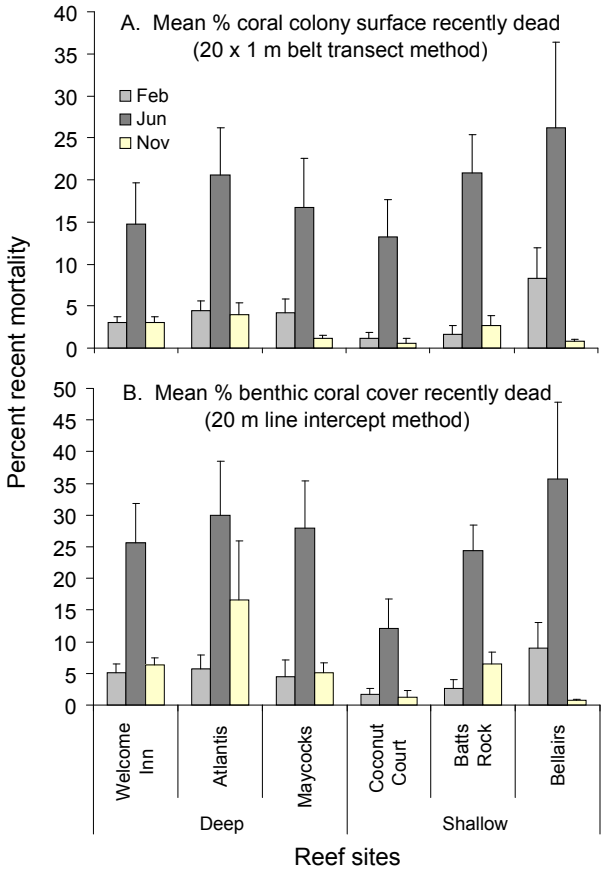

Figure 3: Mean percent loss of live coral at reef sites in Barbados following severe bleaching event of summer 2005, shown by two indices; A – mean estimated % of coral colony surface recently dead, and B – mean percent of benthic coral cover recently dead.

Similar to the trends in bleaching, mortality impacts did not differ significantly between shallow and deep reefs in February nor June 2006 (U > 86, P > 0.05 in both cases), but appeared greater on deep reefs than shallower reefs by November 2006, at least for the benthic coral cover index (Mann Whitney for coral cover: U = 54.5, n = 30, P = 0.015, Fig. 2; cf. colony surface: U = 70, n = 30, P = 0.078).

The severity of mortality impacts differed among coral species, but the trend was similar (Table 2). All species experienced the highest levels of mortality in June 2006, with the exception of *Favia fragum, Siderastrea radians* and *Millepora complanata* (Table 2). *F. fragum* and *S. radians* suffered very high levels of bleaching but low mortality throughout, whilst the milleporids suffered high levels of bleaching and very high early mortality, with *M. squarrosa* eventually disappearing completely from survey transects (Table 2).

Bleaching response was not always indicative of the longer term mortality response across all species. For example, among the most commonly observed species, *Agaricia agaricites*, *Montastrea annularis*, *Porites porites* and *Millepora alcicornis,* all suffered initial bleaching of more than 70% of all colonies and cumulative mortality in excess of 30% of colony surface (Fig. 4). In contrast, *Diploria strigosa* and *Favia fragum* experienced more than 70% bleaching but cumulative mortality was less than 12% for these two species, and *Colpophyllia natans* had very low level of bleaching (< 10%) but more than 30% mortality (Fig. 4).

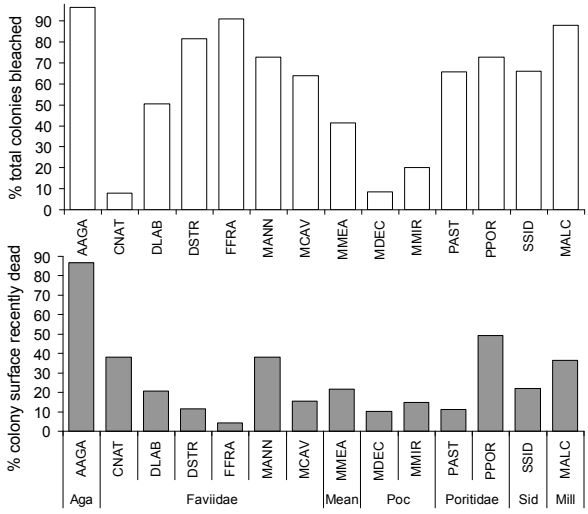

Figure 4. Initial bleaching and cumulative mortality impacts shown for the most common coral species (> 50 colonies per survey) over the period September 2005 to November 2006, grouped by family. Initial bleaching was recorded in September/October 2005. Cumulative mortality represents the sum of 'recently-dead' colony surface recorded in February, June and November 2006. Species codes are given in Table 2.

Table 2: Summary of bleaching and mortality census data for six reefs in Barbados shown for all colonies by species. Data were collected along five 1x20 m belt transects at each reef and are presented as percent of total colonies bleached by species, and percent of colony surface recently dead over all colonies by species.

Discussion

Sea water temperatures and accumulated heating stress through the summer and fall of 2005 were unprecedented for the Caribbean region (Wilkinson and Souter 2008). Conditions in Barbados were no exception and resulted in the worst coral bleaching event ever recorded in this region (Oxenford et al. 2008). Similar claims have been made for other islands of the Lesser Antilles, where the hotspot developed and remained for many months (see NOAA/NESDIS archived database; Wilkinson and Souter 2008).

Although the initial mortality impact on corals was low in Barbados compared with many other locations (Oxenford et al 2008), prolonged bleaching resulted in delayed mortality with high losses of live coral, comparable to elsewhere in the Lesser Antilles (Bouchon et al 2008; Woody et al 2008).

The highest losses of live coral occurred 9 to 10 months after the initial onset of the bleaching event. Corals in Barbados did not appear to die as a result of any described syndrome. Incidence of coral disease was negligible throughout the surveys, in contrast with other reports from the Lesser Antilles (e.g. French West Indies and the US Virgin Islands) where infections were reported to be the primary cause of early bleaching induced coral mortality (Miller et al. 2006; Muller et al. 2008; Bouchon et al. 2008).

Differences in mortality estimates between the two indices used in this study and the delayed onset of mortality in Barbados compared with elsewhere serve to illustrate the importance of standardising methodologies and extending the time-frame over which reefs are surveyed when drawing conclusions about the impact of an event and/or making comparisons among geographically separated sites.

The difference among species in their bleaching and mortality response to the hot water event was marked, but relatively consistent among the few detailed reports from the region with *Agaricia agaricites*, *Colphyllia natans* and *Montastrea annularis* showing particularly high mortality (Woody et al. 2008). Differences in behavioural response such as the ability to increase the level of heterotrophic feeding (Grottoli et al. 2006), and in coral host and symbiont genetics (Berkelmans and van Oppen 2006) certainly contribute to the variation in resistance among species, but are not well understood.

This event marks the most extreme coral bleaching experienced by Barbados reefs on record and corroborates the prediction of more frequent and more severe mass coral bleaching events in the Caribbean with the current trend of global warming (e.g. McWilliams et al. 2005). The study also represents the first quantitative examination of mortality response to mass bleaching in Barbados and indicates the severe ecological impact with cumulative losses of 42.4% and 31.3% of live coral cover from deep and shallow reefs respectively. High losses in live coral cover have significant social and economic implications for Barbados, which relies on healthy reefs for marine-based tourism, coastal protection, and small scale reef-associated fisheries (NCSD 2004). The high coral mortality outcome certainly emphasises the vulnerability of tropical small island developing states (SIDS) like Barbados, with a high reliance on healthy marine ecosystems, to the progression of global warming. It further emphasises the urgency for improved national conservation and coral protection measures to mitigate local stressors and improve reef resilience, whilst continuing to lobby for international action to reduce climate change.

Mapping reef structure and bathymetry in Belize using Cobra-Tac

P. Stetson[1], B. Shank[1], P. S. Lobel[1]

1) Boston University, Department of Biology, 5 Cummington St. Boston, MA 02215, USA

Abstract. The Cobra-Tac underwater navigation system (RJE Int, Irvine, CA) was evaluated for its mapping capabilities in shallow (< 20 m) hard- and soft-bottom reef habitats. This study was conducted on the lagoon reefs around Wee Wee Caye, Belize. The Cobra-Tac was created as an autonomous underwater diving navigation system that measures depth and altitude for hydrographic and position mapping. It computes its geographic position underwater using a fluxgate compass and a Doppler velocity log. Our objective was to assess the Cobra-Tac's effectiveness as a measuring tool for the rugosity of reef structure and for mapping bathymetry. We found that the accuracy, density, and breadth of data collection are dependent upon speed of travel and altitude above the bottom. Also, multiple passes over the desired area may be necessary to best define the underwater topography in detailed resolution. One advantage over boat-based systems is that Cobra-Tac is diver operated and can be taken into shallow and complex habitats. Provided that the limitations of the system are understood, the Cobra-Tac is a powerful tool for easily mapping the topography of small-scale and shallow marine systems. It produces intelligible and informative bathymetric maps within 30 minutes of data download that are then ready to be used to delineate transects for biotic surveys.

Key words: reef mapping, underwater navigation, Cobra-Tac, Doppler device

Introduction

Coral reefs are complex habitats that support diverse assemblages of biota. The structural rugosity of a reef can be a good predictor of the diversity and abundance of organisms that inhabit reefs (Grigg 1994). While the topographic complexity of reefs is expected to be influential in the abundance of most fishes (Luckhurst and Luckhurst 1978; Gratwicke and Speight 2005), attempts to correlate reef structure with fish density and species richness has met with mixed success. For example, Chapman and Kramer (1999) found a significant relationship between rugosity and fish density for only 10 out of 26 studied species. McCormick (1994) compared six different metrics of topography as indicators of fish abundance. He found a significant relationship in only 18 of the 50 species studied. The reason for this apparent disconnect between topography and fish abundance was due to the difficulty of measuring reef topography on a scale appropriate to the fish survey (McCormick 1994). The most common method for mapping topographic complexity is the chain method developed by Risk (1972). This method is typically applied over areas of 10 m or less. Although this scale may be adequate for smaller fishes, it may not capture the habitat at scales relevant to larger fishes (McCormick 1994; Bartholomew et al. 2008). Some researchers have recognized the scaling problem. When the spatial scale of habitat characterization was expanded, it resulted in better estimation of the abundances of roaming fishes (Friedlander and Parrish 1998; Abesamis et al. 2006; Mumby et al. 2007; Bartholomew et al. 2008). New quantitative methods of characterizing topographic complexity in shallow marine systems at larger scales (100's of meters) have not been fully developed.

Current reef mapping technologies are time intensive. Sidescan sonar provides habitat assessment over broad areas, but topographic relief is difficult to extract. Sidescan sonar does not offer consistent resolution, as the relative height of the towfish above the bottom can vary during operation. Diver surveys provide accurate biological inventories but the collection of directly comparable quantitative topographic information is difficult. Other methods exist (Risk 1972; Smith et al. 1975; Aronson et al. 1994; Mumby et al. 1997; Maeder et al. 2002; Fossa et al. 2005), but each of them, while effective in gathering some metrics, is limited by cost, time, quantity, or quality of data.

To address this need for improved bathymetric mapping technologies, we tested the Cobra-Tac

autonomous underwater navigation system (RJE International) for its potential to produce quick, high-resolution bathymetric maps of reef habitats. Cobra-Tac is a diver-operated acoustic Doppler profiler that utilizes tracking technology for underwater navigation.

Study Sites

The study sites were in Belize, Central America. Wee Wee Caye is a small island in the lagoon of the Mesoamerican Barrier Reef off Belize (16.76474288° N 88.142522° W). Southwater Caye is a small island abutting the barrier reef at 16.813567° N 88.080172° W. The surveys were performed in December of 2007.

Methods

Surveys with Cobra-Tac were conducted using a swimming or towed diver. Swimming divers navigated and operated the unit at various depths. A diver (or snorkeler given calm conditions and low speeds) was towed behind a boat (at speeds of 2-4 kt). The boat-towed setup allowed us to compare GPS readings directly with the Cobra-Tac navigational calculations.

The most effective data collection method involved towing or swimming the Cobra-Tac in a tight organized grid. In all cases, holding the unit absolutely horizontal so that the Doppler is aimed directly downwards is critical.

The unit requires the user to input initial GPS coordinates at the surface. The diver then swims the study site while the unit records the location and depth of four points (one for each beam) at one-second intervals throughout the survey. After the completion of the survey, post processing is necessary to create a three-dimensional map of the site. Maps are created with Surfer (Scientific Software Group) or the data can be exported to other software platforms.

Results

The Cobra-Tac and supplied software were readily capable of producing a three-dimensional image of a study site in about 30 minutes of post-processing. In addition, Matlab (Mathworks Inc.) was applied to the Cobra-Tac data to examine details and consistency of the original Cobra-Tac data set.

The Cobra-Tac's navigational accuracy was tested by performing swims along irregular tracks and then navigating back to the start point. Table 1 shows three trials where the start/end location was the same fixed structure. The results from these trials show an accumulated error between 8 and 31 m, which is well within the manufacture's specified 3-5% error. Accuracy could be improved by setting reference points along lengthy surveys for post-dive calibration.

Table 1: Distances traveled during each dive and the error from the starting point Cobra-Tac showed at the end of each dive

Approx. Distance Traveled (m)	Error in recognizing return to starting position (m)
500	8
1600	31
1600	27

The spur and groove reef mapped at Southwater Caye was created with a single pass of the Cobra-Tac operated by a snorkeler (Fig. 1). The spur and groove formations are clearly visible in the figure, but much fine-scale irregularity was lost due to the smoothing functions applied by the supplied software.

The channel immediately west of Wee Wee Caye was also mapped (Fig. 2). The map was created with 6 passes along the longer dimension of the channel, each the length of the channel in a single grid-formation tow. The island and the slopes of the shoals to the west and north are clearly visible in the image. The bathymetry of the channel-bottom, which otherwise is too deep to see from the surface, is also well defined.

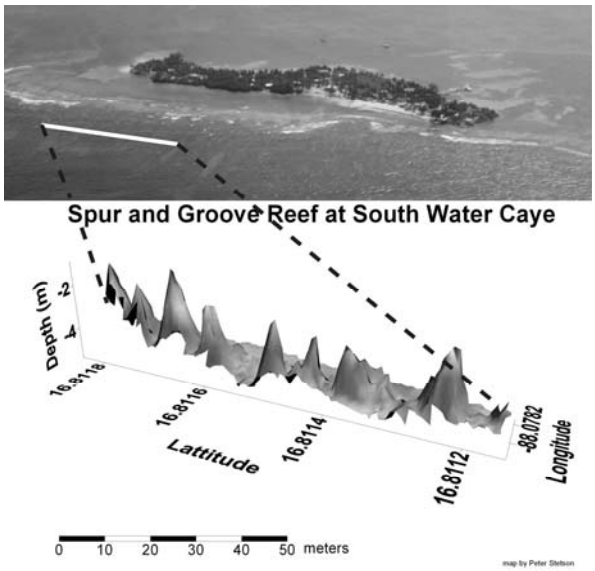

Figure 1: 3-D surface map (bottom) of single-pass transect over spur and groove reef at SouthWater Caye, Belize. The sampled area corresponds to the white line shown in the upper image.

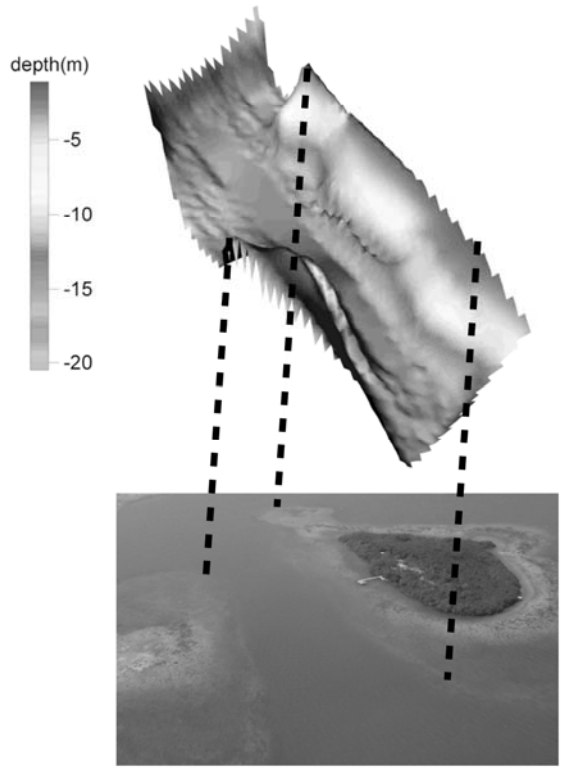

Figure 2: Surface map of channel west of Wee Wee Caye, Belize on top of aerial photograph of the caye. Dashed lines illustrate how the images line up.

To illustrate the necessity of adequate site coverage, the channel data set (Fig. 2) was reanalyzed using subsets of the total number of passes. Revised surfaces were created from these selected passes over the channel (Fig. 3). Too few passes resulted in inaccurate topographic detail.

The following formula was developed to determine the best mapping strategy for a given area in terms of how many passes (or tracks) are needed to yield optimum bottom coverage. The minimum number of passes, ***np***, over a study site is equal to the width of the site, ***w***, divided by the breadth of the beam angles. The breadth of the beam angles is equal to 2 times the height of the unit above the bottom, ***h***, multiplied by **tan (30)**, where 30° is the beam angle (Equation. 1).

(Equation 1) $$np = \frac{w}{2h * \tan(30)}$$

Artifacts in the data were sometimes a problem (Fig. 4) and difficult to differentiate with the Cobra-Tac supplied software (Surfer). It was necessary to post-process the data in Matlab in order to investigate apparent anomalies and remove artifacts, such as the extreme peak and pit seen in Fig. 4. The pit occurred in what we thought was a flat sandy bottom. The peak and pit formation were the result of the unit briefly tipping beyond level, allowing the unit to register far away points as an apparent bottom (Fig. 5).

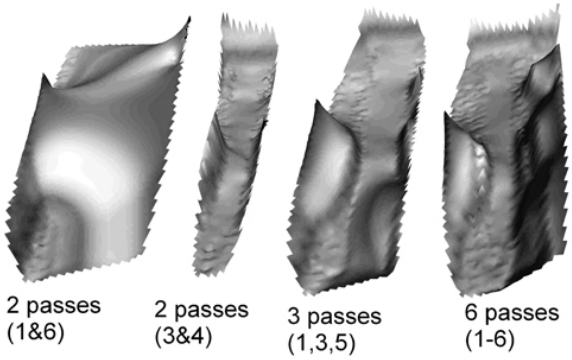

Figure 3: Surfaces created with different combinations of passes over the study site: passes sequentially ordered 1-6 going from west to east. 1 and 6 are the outermost passes of the 6 total.

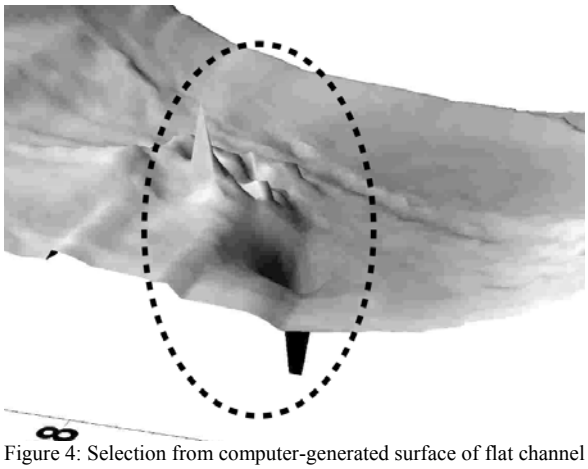

Figure 4: Selection from computer-generated surface of flat channel bottom, interpolated from bad data which resulted in anomalous structures visible within the dashed ellipse.

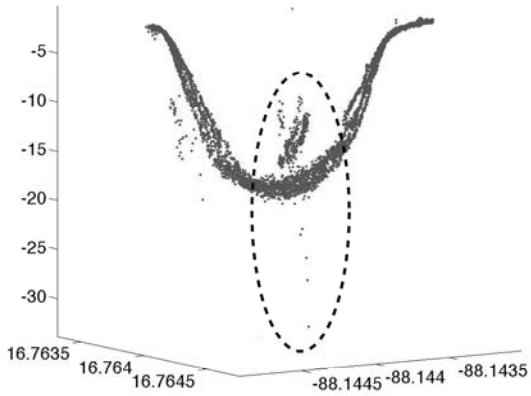

Figure 5: Matlab generated plot of cross channel survey data points as individual dots. Dotted ellipse indicates suspected outlier points, especially in lower portion of plot (below 20 m on z-axis).

Error in mapping can also result if all four of the Doppler beams do not record. The number of beams

used to collect data and the complexity of surface recorded is related (Fig. 6). Repeated transects over the same location allow for more complex surfaces to be defined up to the limit of the beam resolution. The beam resolution can be calculated, in theory, based upon the specification of a 1.4° beam width. For example, at a height of 10 meters above the bottom, the spatial resolution is 0.28 m^2.

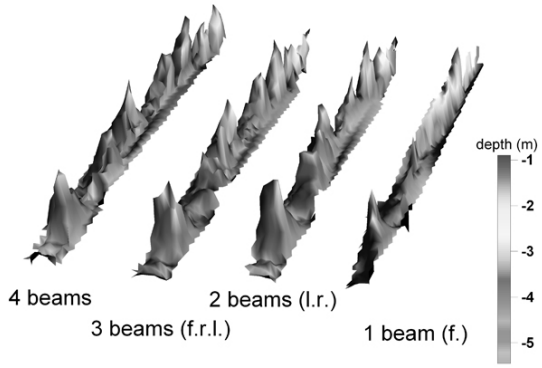

Figure 6: Surfaces created from 4, 3, 2 and 1 beams of the 4 beams on the Cobra-Tac. f= front, r= right, l= left. The complexity and accuracy of the 4 beams surface is significantly greater than that of the surfaces created from fewer beams.

Discussion

Cobra-Tac is a highly portable device that is capable of producing an accurate bathymetric map of a study site within 30 minutes of exiting the water. Waypoints of items of interest can be added while mapping underwater and displayed on the maps produced. The unit does not require a boat; therefore, it can be used in areas inaccessible to vessels. It can be towed behind a boat (with diver) but does not require any specialized apparatus beyond a towrope.

Cobra-Tac is not limited to working from the surface. This allows the device to be kept at a constant altitude above the bottom by a diver when moving over structurally complex habitats. Thus providing consistent resolution of bottom topography. The data are easily incorporated into GIS software, such as ESRI's ArcScene and ArcMap. With a luggage case for the unit and a laptop for data-processing, one can travel very easily with the Cobra-Tac.

The Cobra-Tac was able to map the bathymetry of local areas well. While the accuracy was fine enough to create bathymetric maps, our preliminary data were insufficient to assess if the Cobra-Tac will be a feasible tool for measuring fine scale rugosity (< 10 cm).

Data artifact creation is only avoided by maintaining vigilance while operating the unit and keeping it level. Data anomalies are easily investigated with Matlab, where a few outlying points can be recognized and removed. A shortcoming of the system is that the tilt sensor does not automatically filter data.

Overall, Cobra-Tac does create high-resolution bathymetric maps of reef areas. The effort of collecting and post-processing the data is simple and easy. A bathymetric map of appropriate resolution can provide a permanent record of the reef slope and medium to large-scale rugosity. Sampling over larger geographic scales (100's of meters) presents the opportunity for creating new metrics for habitat complexity at a landscape-scale. Such scales are more relevant for larger, commercially important fishes (Bartholomew et al. 2008). Additionally, Cobra-Tac is a non-invasive technique that does not require physical contact with the bottom or extraction of organisms or live substrate for laboratory measurement.

A device such as the Cobra-Tac has the potential for mapping changes in the structural complexity of reefs that may occur due to physical disturbance or coral mortality events. This is important, not only for monitoring the reef structure itself, but also because the loss of reef habitat results in decreased reef-associated fish biomass (West and Salm 2003). Such large-scale changes in reef structure have generally not been defined quantitatively over time due to technological limitations. Further field-work (in progress) will determine if the Cobra-Tac has the resolution and reproducibility to solve this challenge.

Abstract. A synoptic perspective of reef biogeochemical dynamics and community structure was revealed using new technologies and methods designed to enable high resolution underwater habitat assessment with non-invasive monitoring capabilities and rapid information output. A towed, chemical sensor platform (TETHYS) and a diver-based, benthic imaging system (SCUBA COP) were developed to compare reef architecture and seafloor morphology across centimeter to kilometer spatial scales, and resolve sub-meter variability in ambient water chemistry across 300 km seascapes. Acoustic bathymetry, stereo-optical imaging, *in-situ* underwater mass spectrometry, and fluorometry data were coupled with precision navigation to enable multi-parameter biogeochemical and structural comparisons of coastal and island coral habitats surrounding Coiba Island, a UNESCO World Heritage site in Pacific Panamá. Baseline chemical data [O_2, CO_2, CH_4, N_2]; and digital 3-D reef mosaics were coupled with SCUBA diver transect data, High Definition video, oceanographic time series from a cabled underwater observatory, Landsat and SeaWiFs satellite imagery to create and validate comprehensive, thematic chemical and benthic habitat maps. This integrated approach shows considerable promise for locating, predicting and quantifying natural and anthropogenic environmental stressors affecting the distribution, diversity and health of tropical coral communities.

Key words: coral reef ecology, benthic optical imaging, biogeochemistry, mass spectrometry, Panamá, Coiba

Introduction

Coral reefs are structurally intricate and complex biogeochemical systems existing in highly dynamic fluid environments. Efforts to link ecologic pattern to process in these variable and adaptive habitats requires precision, multi-scale, spatio-temporal information in order to establish quantitative baselines or accurately identify emergent or alternate stable states (Ratze et al. 2007).

Laboratory methods are limited in their ability to detect gross biogeochemical or metabolic changes of coral reefs over large spatio-temporal scales and may exhibit associated systematic sampling bias. Although SCUBA divers can intensively sample small areas *in-situ*, over brief intervals, physiological constraints makes replication costly (in terms of data density per diver-hour) and inherent information loss occurs through sacrifice in resolution when increasing observational domain (Lam et al. 2006; Hill and Wilkinson 2004). Limited *in-situ* capabilities generate sparse, spatially and temporally disconnected data sets with inadequate overlap, especially when used to corroborate larger scale processes or patterns (Garza-Perez et al. 2004; Mumby et al. 1999).

While coral reef deterioration along the Eastern Tropical Pacific (ETP) coasts of Panamá and Costa Rica were first identified nearly thirty years ago, understanding of the complex biotic-abiotic interplay which resonates and shapes coral communities within this Pacific biological corridor remains elusive (Glynn and Maté 1997; Guzman et al. 2004).

The focus of this manuscript is to convey new, ecologically relevant information emerging from the use of synoptic methods developed to quantify and characterize the architectural and chemical environments of coral communities across multiple temporal and spatial scales. Sites were chosen in the Gulf of Chiriquí (GOC) Panamá among island clusters and coastal zones which geographically delimit the current boundaries of the 216,543 hectare Marine Protected Area (MPA) of the Coiba Island National Park (Fig. 1).

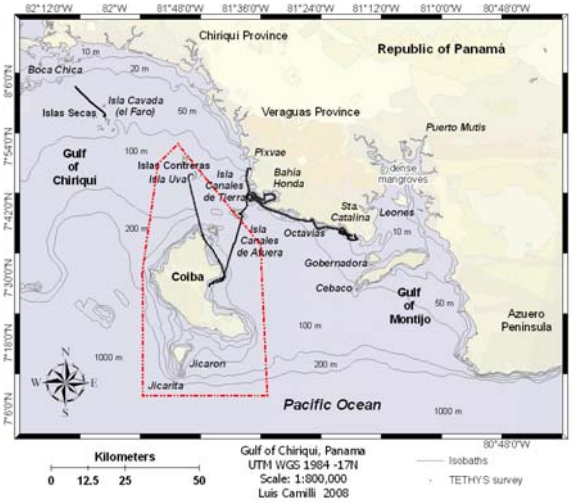

Figure 1: Pacific Panamá Gulf of Chiriquí (GOC) showing Coiba MPA boundary (red dashed line), coarse bathymetry, SCUBA dive sites, and TETHYS towfish survey (black line). Total TETHYS swath distance was 300 km with ≈ 36,000 discrete chemical measurements at 3 m spatial resolution (0.25 m - 15 m) deep.

Material and Methods

Towed, in-situ Mass Spec Chemical Surveys

In February 2007, real time, *in-situ* measurements of chemical species (i.e. O_2, CO_2, CH_4, N_2) chlorophyll-a (chl-a), chromophoric dissolved organic matter (CDOM), salinity, temperature and depth were accomplished using a towed chemical sensing platform equipped with a TETHYS underwater mass spectrometer, CDOM and chl-a fluorometers and a Conductivity, Temperature, Depth (CTD) sensor.

TETHYS was configured to monitor selected ion peaks corresponding to CH_4, H_2S, nitrogen isotope ratios (^{14}N -^{14}N and ^{14}N -^{15}N), O_2, Ar, and CO_2. Additionally, full spectral scans of 1-200 atomic mass units (AMU) enabled identification of hydrocarbons, industrial and toxic compounds. Mass spectrometer data were normalized to Argon which is biologically inert and serves as a natural tracer in ambient seawater. A single beam acoustic depth profiler collected bathymetric data while a Global Positioning System (GPS) device recorded position which was synchronized with TETHYS data based on internally logged time stamps (Camilli et al. 2007).

Average tow velocity was 2.5 m/s with each transect lasting about 6 hours. An oscillating depth or "Tow-Yo" approach was conducted by periodically slowing the boat velocity so that the towfish would perform a vertical cast, and increasing boat velocity until the instrument returned to its near surface depth (- 0.5 m). This technique created a sinusoidal profile of the water column at regular time intervals and was also employed when substantial change was detected in the surface waters.

Automated Diver Imaging Sled and SCUBA surveys

The SCUBA-diver operated Chemical Optical imaging Platform (SCUBA COP) is a self-contained dive sled that collects 12-bit, 1.4 megapixel video-rate stereo image pairs and simultaneously measures water depth, temperature, and dissolved [O_2]. Two laterally mounted and synchronized strobes minimize exposure time and variable effects of ambient lighting. SCUBA COP records mission start and end GPS surface position and continuously records dynamic vehicle trajectory and attitude (360° angular motion over 3 axes). Altitude above sea floor is triangulated based on stereo field of view (Camilli et al. 2007).

Seven dive locations were chosen to represent GOC areas with coral cover, and a stratified approach spatially randomized transects at each dive site using a list of random compass bearings and distances (10-100 m) from the dive vessel. Three, 50 m, tape-based linear transects per site were oriented perpendicular to shore to standardize swath coverage. Each transect was spaced a minimum of 20 m apart. Serial transects were captured at 2 m altitudes by one diver equipped with a Sony HDR-UX1 digital High Definition (HD) video camera followed by a second diver operating the SCUBA COP stereo imaging system. A third diver employing a Point Intercept Transect (PIT) method manually surveyed the same transects, defining 10 benthic categories at 0.5 m intervals below the tape (Reef Check 2004; Page et al. 2001).

Results

Reef Water Chemistry in the Gulf of Chiriquí

At an average tow depth of 2 m across the GOC, mean water temperature was 28.14 °C and salinity was 31.95 practical salinity units (psu) (N=35,953). Temperature and salinity for all coastal surveys were 28.7 °C and 31.85 psu, while offshore regions measured 29.9°C and 31.24 psu respectively.

Contrary to expectations, coastal transects over a shelf ≤ 30 m deep, homogeneously exhibited, lower temperature and higher salinity than offshore transects over deep water (≥ 50 m). The Panamá LJL Underwater Tropical Observatory (PLUTO), located at 18 m depth within the coastal survey area concordantly measured high frequency time series (≈10 min) oscillations in temperature ranging from 16° C to 28°C, and salinity fluctuations ranging from 27 to 32 psu over 3 m tidal amplitudes. Preliminary seiche calculations using measured wind velocity and water depth suggest that this effect is not a result of localized surface wind stress.

Low levels of dissolved O_2 were noticed between Canales de Afuera and Canales de Tierra islands and between the Islas Secas group to Boca Chica.

Comparatively high O_2 levels were observed near Isla Uvas and again northwest of Isla Coiba. Average [chl-a] for inter - island transects were higher 0.24 µg/L (+/- SD 0.02) than coastal transects 0.16 µg /L (+/- SD 0.06). The transect leg from Boca Chica to the Islas Secas group contained the highest mean [chl-a] 0.31 µg /L (+/- SD 0.05). Northwest along the coast, near the bay of Pixvae, chlorophyll was often near zero 0.05 µg /L (+/- SD 0.05) and low again going east along the coast until Santa Catalina where values increased to 0.20 µg /L (+/- SD 0.08).

Along the coast, CDOM concentrations averaged 5.50 Quinine Sulfate Units (QSU), and 2.87 QSU offshore. CDOM and Chl-a adjacent to offshore island reefs are shown in Fig. 2. Strong vertical gradients and localized anomalies dominated coastal regions of the Eastern GOC with CDOM reaching an order of magnitude greater (≥50 QSU) in the bay of Bahia Honda.

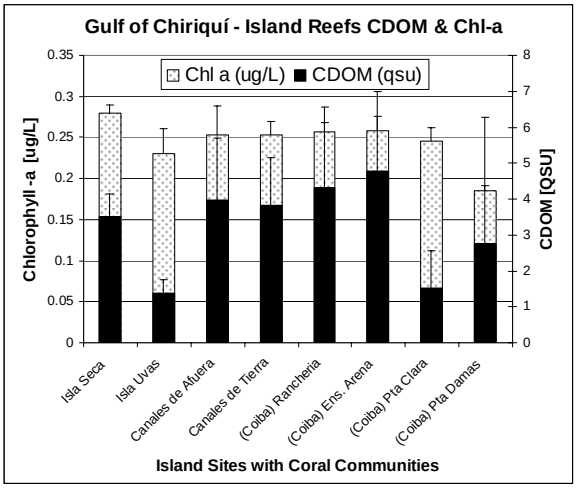

Figure 2: Comparison of mean chlorophyll-a [µg/L] and CDOM Quinine Sulfate Units [QSU] concentrations from TETHYS TowFish surveys of offshore islands in the Gulf of Chiriquí (≈15,000 samples). Error bars represent 1st standard deviation.

Survey transects provide evidence that the variability of nutrient mixing in these water masses can be extreme (Fig. 3). For example, a small plume of brackish water with salinity < 10 psu and high CH_4 was found subsurface near the coast of Santa Catalina (Fig. 4). Nitrogen isotopic (^{15}N) enrichment (i.e. low ^{14}N : ^{15}N) patterns were also observed in the western GOC between the Secas Islands and the Boca Chica mangrove mainland. A negative correlation between CO_2 and salinity (r = - 0.451; n = 842) suggests that freshwater input near island regions could be more important in determining CO_2 levels than pelagic water sources where carbon would ostensibly originate from atmospheric CO_2 drawdown. Offshore subsurface CDOM weakly correlates with salinity (r = + 0.245; n = 842). The reverse is true for the strong negative correlation (r = - 0.805; n = 260) between CDOM and salinity in the central GOC, supporting the idea that dissolved organic material input to these reefs may originate primarily from terrestrial sources.

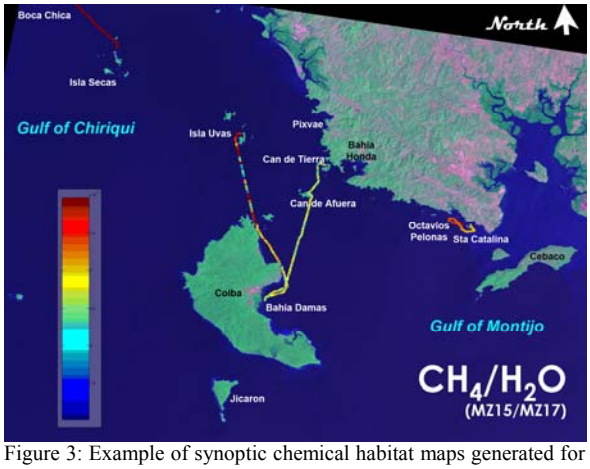

Figure 3: Example of synoptic chemical habitat maps generated for each bioactive parameter measured across survey areas. Color gradients indicate concentrations [mass (M) to charge (Z) ratios] of each element. Simultaneous chemical and GPS data were georectified and integrated into Landsat TM year 2000 satellite imagery to produce high resolution GIS composite images.

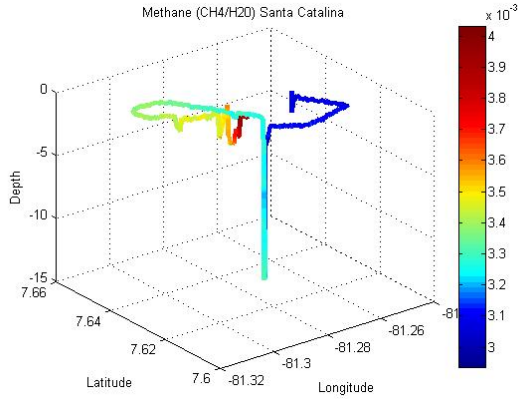

Figure 4: TETHYS sinusoidal profile and deep cast revealing (3-D) methane concentrations in the water column surrounding the island (and village) of Santa Catalina (reference Fig. 3). Color gradient areas in red indicate higher levels of methane (M/Z) and areas in blue indicate lower levels (dimensionless units). Depth = meters; latitude / longitude = degree-decimal-minute.

SCUBA surveys results

For the purposes of standardizing comparisons between methods, percent cover of each of ten categories was used to characterize the benthic substrate and sessile organisms across dive sites. The Reef Check method tends to overestimate sand cover and underestimate algal cover and coral rubble (Fig. 5). Both methods function similarly well in determining hard coral, silt, and rhodolith percent cover. Structurally complex, carbonate architectures dominated by *Pocillopora damicornis* and *P. Elegans* were encountered on northern (unexposed) shores of islands in shallow (<10 m) waters over a continuous

sloping shelf (i.e. Islas Contreras and Islas Uvas). More diverse, discontinuous and patchy coral communities were found on shallow rocky shelves on southern (wave exposed) shores. Soft coral, gorgonian and sponge communities were most often encountered in large boulder areas with swift currents ($\geq$ 15 cm/s) and colder water ($\Delta \geq$ -5°C) at depths 15 to 20 m. Hard corals, if present, existed in isolated patches closer to the surface, interspersed between heavily encrusted boulders. A filamentous red-brown algae (Cyanophyte) covered sandy areas (esp. Bahia Damas, Coiba) and stable sea grass communities were conspicuously absent in shallow sandy areas. Dense calcareous red algae (Rhodolith) beds covered shallow areas of some islands; (i.e. 40 % cover in Isla Canales de Afuera). Hard coral species encountered across dive surveys include members of Agariciidae: *Gardineroseris planulata, Pavona clavus, P. gigantea, P. varians, P. chiriquiensis*, *P. frondifera, P. maldivensis;* Pocilloporidae: *Pocillopora elegans, P. damicornis*, *P. capitata, P. eydouxi;* Poritidae: *Porites lobata, P. panamensis;* Siderastreidae: *Psammacora stellata;* Fungiidae: *Cycloseris curvata; Milleporadea*: *Millepora intricata;* Dendrophyllidae: *Tubastraea coccinea*.

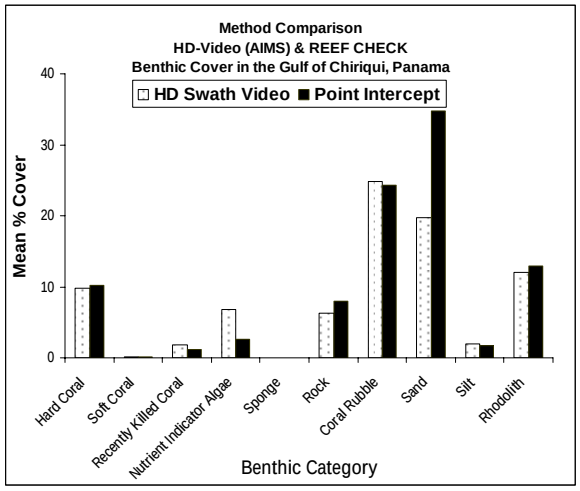

Figure 5: Reef Check (2004) and High Definition video (Australian Institute of Marine Science video protocol) using identical transects to assess 10 benthic cover categories across 7 dive sites in GOC.

The HD-video analysis (Fig. 6) indicates Isla Uvas and Isla Canales de Afuera with equally high coral cover (18.4%). Isla Canales de Tierra, near the mainland, was (16.6%). El Foro (Islas Secas) was (4.6%) - the lowest of all the offshore islands. Isla Managua located within the protected coastal bay of Bahia Honda, exhibited even lower (1.3%) coral cover when compared to Punta Miel (4.4%) at the western headland of the same bay.

Significantly more area was surveyed with the SCUBA COP than with HD video and PIT methods. Approximately 500 GB of digital stereo imagery were collected during 6 diving days corresponding to nearly 7 hrs of bottom imagery and 5 km linear data and representing 7500 m^2 area coverage. At this point, the mosaic swath processing can be divided into strips and applied to any subsection of the data ranging from 10s to 100s of square meters. Due to the fact that morphologically different coral species possess uniquely shaped surfaces, texture-based decision algorithms can be employed to automate coral classification from machine vision data. The subset of SCUBA COP mosaic swaths corresponding to the structured linear transects (i.e. PIT and HD video) are currently being used to create and validate automated feature segmentation and classification routines.

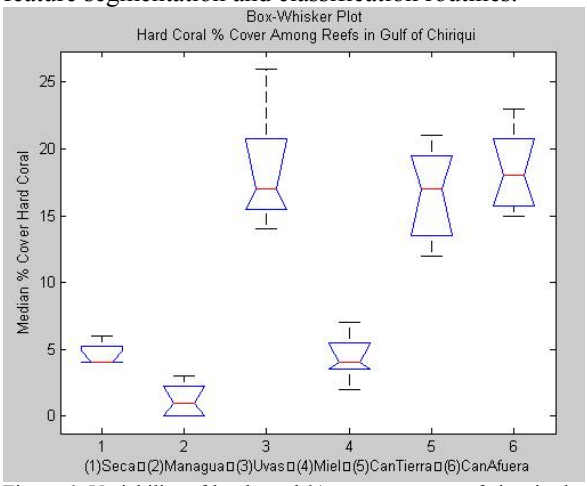

Figure 6: Variability of hard coral % cover among reef sites in the Gulf of Chiriquí. Lower and upper lines of each "box" = 25th and 75th percentiles. Distance between top and bottom = interquartile range. Horizontal middle line = sample median (skewness). Lines above and below the box = total sample extent. Notches in the box = confidence interval about the sample median.

Discussion

Multi-parameter TETHYS data imply that inter-island surface water chemistry (0-12 m) in the eastern GOC is relatively well mixed while shallow coastal areas are periodically exposed to cold water pulses during the dry season (boreal winter). Perhaps deep water originating in the adjacent Gulf of Panamá (or further offshore) is entrained in subsurface circulations that seasonally manifest as internal waves, eroding the thermocline and shoaling turbulently over shallow coastal bathymetry with added effect from orographic lift during large amplitude tides. Regardless of the mechanism, seasonal cold water pulses are regularly being delivered to coral communities, colder and more sustained than previously considered (*sensu*: Glynn and Maté 1997). Although these phenomena are likely influencing reef community structure and associated biochemical processes, unfortunately, subsurface mixing of cold water masses with warmer surface waters (≈10 m depth), and the spatial aliasing inherent in satellite sensors impairs routine remote

observation. The finer spatial-temporal resolution afforded by the TETHYS towfish allowed synoptic visualization of these winter, dry season temperature/salinity patterns and the associated primary productivity in subsurface water across a >100 km swath (Fig. 7).

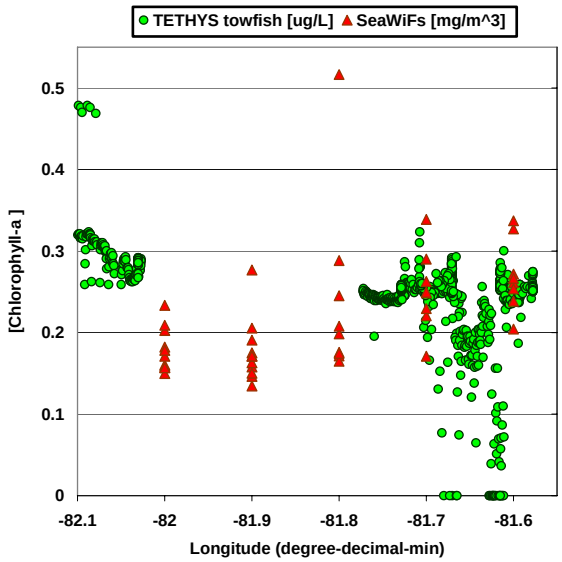

Figure 7: Comparison of *in-situ* TETHYS towfish and remotely-sensed SeaWiFs satellite [chl-a] data plotted along a longitudinal gradient during a time scale of 2 weeks in February 2007. Spatial resolution of SeaWiFs = 9 km^2 and finer spatial resolution of TETHYS towfish = 3 m^2. Data are reported in equivalent units [µg/L] = [mg/m^3]. Coarser SeaWiFs chlorophyll estimates provide an accurate upper limit constraint on sea surface chl-a, but are not able to substantially resolve smaller scale spatial-temporal dynamics over the same domain.

Contextually elevated CH_4, ^{15}N, CO_2, and [chl-a] coupled with lower O_2, suggests more eutrophic waters extending from the Boca Chica mainland into the central GOC. Although stretches of oligotrophic water were observed along the coast north and east of Coiba during this dry season survey, the risk of eutrophication along the Coiba Island corridor could be elevated especially during the wet season. Panamá experiences high seasonal rainfall (>3000 mm/yr) and these reefs could be severely impacted if corals are exposed to chronic runoff of nutrients originating from soil erosion, fertilizers or untreated sewage. Detrimental effects of NO_3^- enrichment (Schlöder and D'Croz 2004) in *P. damicornis* might be of great relevance for local conservation because it is the major reef-building coral in the ETP; a biotope known for intrinsically low coral diversity. GIS analysis of year 2000 Panamá Census data indicates >103,000 people inhabit the Gulf of Montijo drainage basin with 24 major tributaries eventually flowing into the eastern GOC (L. Camilli, unpub. data). Agricultural land use pressure, herbicides, erosion, unregulated coastal construction, mangrove deforestation, and increases in septic effluent in surrounding areas poses a tangible threat to the biological integrity of coral reefs ecologically linked with the Coiba MPA.

Coral reefs are complex adaptive systems that can experience accelerated habitat change due to their proximity to natural and anthropogenic disturbances worldwide. Semi-automated, *in-situ* chemical and optical sensor innovation reduce survey time and enhance the ability to effectively focus and tune experimental efforts. By resolving multi-dimensional ecologic and oceanographic variability in greater detail, the novel analytic methods demonstrated in this project complement remote sensing techniques, field manipulations, laboratory experiments, and become a critical nexus in accurately coupling pattern to process in the ocean environment.

Acknowledgements

Field surveys were funded by the Wildlife Conservation Society, the Ocean Life Institute and the U.S. Fulbright Program. The Liquid Jungle Laboratory provided lab facilities. The University of Sydney Australian Centre for Field Robotics and the Woods Hole Oceanographic Institution provided engineering support for sensor development. The Autoridad Nacional del Ambiente (ANAM) supplied research permits. Thanks to José Miguel Guevara of ANAM for GIS assistance; Dr. Juan Maté of the Smithsonian Tropical Research Institute for coral species verification and Bryan Becker and Rachel Fulton for SCUBA survey assistance.

Is sponge bioerosion increasing?

C.H.L. Schönberg[1, 2], J.-C. Ortiz[1]

1) Centre for Marine Studies, The University of Queensland, St. Lucia, QLD 4072, Australia

Abstract. We tested the hypothesis whether bioerosion is likely to increase on stressed coral reefs, using bioeroding sponges as a key group. A survey was conducted on the central Great Barrier Reef before and after two major bleaching events. While coral cover was slightly reduced, total bioeroding sponge abundances significantly increased from the first to the second survey (by 150%, $p < 0.001$). *Aka mucosa* became more common on the upper reef flat, and symbiotic bioeroding sponges proliferated on the lower reef flat and slope. Both groups are able to attack live coral. As typical after disturbance events, homogeneity of the sponge abundances was more pronounced after bleaching. Due to increased availability of settlement area and reduced space competition, we expect bioeroding sponge abundances and bioerosion rates to rise globally and would like to encourage more intensive field investigations on this group.

Key words: *Cliona*, *Aka*, bioeroding sponges, abundances, community shift

Introduction

On healthy reefs and under normal conditions, bioerosion is balanced or exceeded by carbonate accretion (Goreau and Hartman 1963), but this balance can be upset by shifts in environmental conditions or by disturbance events. As a consequence, reef-building organisms may suffer mortality, sublethal damage or stress (Berkelmans et al. 2004). In contrast, bioeroding organisms appear to continue to function normally or can occasionally even become epidemic (Rose and Risk 1985; Vicente 1990). Disturbance-related, changed conditions involve (i) the creation of suitable substrate for the settlement of larvae of bioeroding organisms, (ii) reduced space competition in favor of bioeroding organisms and (iii) reduced resistance of organisms invaded by bioeroders (Rose and Risk 1985). Considering that endolithic bioeroding organisms are relatively sheltered from otherwise adverse ambient conditions (Schönberg and Suwa 2007; Schönberg et al. 2008) and that many are filter feeders that may benefit from eutrophication (Rose and Risk 1985; Holmes 1997, 2000; Holmes et al. 2000; Ward-Paige et al. 2005), a rise in bioerosion appears to be a logical consequence if present trends of environmental deterioration continue. In extreme cases the positive balance of reef accretion will be overridden and bioerosion may prevail.

Sponges are the leading internal bioeroders on many coral reefs (MacGeachy and Stearn 1976). Many successful and aggressive species of bioeroding sponges harbor symbiotic dinoflagellates (Schönberg and Loh 2005), and have been reported to be more bleaching-resistant than corals (Vicente 1990). Reasons for this observation may stem from differences in the symbiosis of corals and bioeroding sponges: the 3-dimensional body of the sponges shelters symbionts from light more efficiently than coral tissue; the sponge G-type symbionts appear to be comparatively stress-resistant (Schönberg and Loh 2005; Schönberg et al. 2008); and the sponges are able to move the symbionts away from sources of stress (Schönberg and Suwa 2007). Recent observations have reported putative increases of bioeroding sponges in the Caribbean (Rützler 2002). However, to date we had no quantitative data on bioeroding sponge abundances both before and after a major disturbance event.

We report findings of a field study before and after bleaching at Orpheus Island, central Great Barrier Reef (GBR). The same survey was conducted in 1997/98 (Schönberg 2001) and in 2003/04. In 1998 and 2002 two major bleaching events significantly affected the study area, mainly killing branching corals (Berkelmans and Oliver 1999; Baird and Marshall 2002; Berkelmans et al. 2004). This presented an opportunity to investigate whether bioeroding sponges suffer from environmental changes as much as other reef organisms or, alternatively, whether bioeroding sponges tolerate environmental changes or even benefit from them. This study attempts to provide insights into possible future trends of reef bioerosion.

Material and Methods

The present study was conducted in the southern part of Little Pioneer Bay, Orpheus Island, central GBR (18°37'S and 146°29'E), mostly on SCUBA and partly by snorkeling. Methods were consistent in the first and second survey: Sponge occurrences were recorded along five 100 x 0.5 m belt transects perpendicular to the shoreline (see Fig. 2 in Schönberg 2001) using a 50 x 50 cm quadrat subdivided into 100 cm^2 squares. Any 100 cm^2 sub-square that contained bioeroding sponges was counted and then related to the amount of available calcium carbonate (see also Chiappone et al. 2007). Sponge occurrences are here represented as percentages per available substrate per square and then averaged over each reef zone (Table 1). Reef zones and sponge species were categorized as in the first study (Schönberg 2001), with the zones being defined as:

A) sand flat with only very little suitable substrate for bioeroding sponges, substrate often buried
B) mixed zone with sand patches, rubble, blocks and small live, massive corals with dead tops
C) coral pavement where mostly dead corals form a more or less continuous ground cover
D) branching coral zone, mostly reduced to rubble during the second study
E) reef relief, including live corals in patchy distribution

The sponge groups were:

1) the encrusting growth form of *Cliona orientalis* Thiele, 1900 (for information on growth forms see e.g. Schönberg 2008)
2) brown papillate bioeroding sponges with a papillar diameter > 2 mm (dominated by the papillate growth form of *C. orientalis*)
3) brown or orange papillate sponges with a papillar diameter < 2 mm (mainly including *Cliona caesia* (Schönberg, 2000) and *Pione vastifica* (Hancock, 1849), but to a smaller extent also *Cliona mucronata* Sollas, 1878 and *Cliona vermifera* Hancock, 1867)
4) yellow or orange papillate sponges with a papillar diameter of > 2 mm (*Cliona celata* Grant, 1826 *sensu* Schönberg 2000, *Cliothosa hancocki* [Topsent, 1888] and *Cliothosa aurivillii* [Lindgren, 1897])
5) *Aka* spp. (vastly dominated by *A. mucosa* [Bergquist, 1965] *sensu* Schönberg 2000, but also including the rare *A. paratypica* Fromont, 1993)
6) *Zyzzya criceta* Schönberg, 2000
7) other, comparatively rare bioeroding sponge species

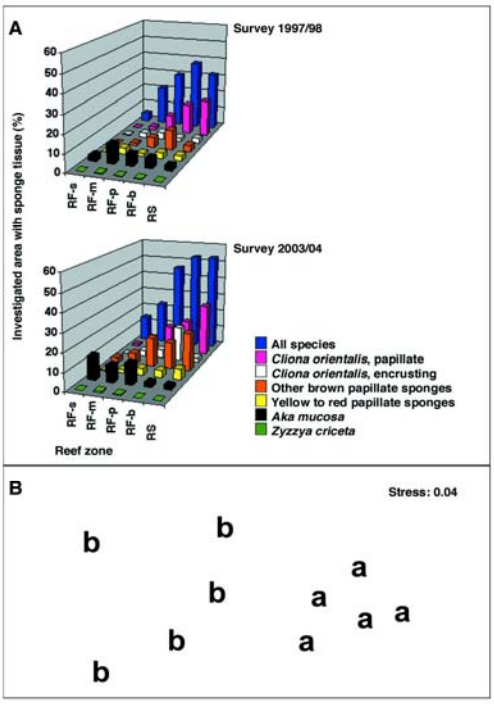

Fig. 1. Bioeroding sponge distributions at Orpheus Island. A: Increase in bioeroding sponge abundances on the central Great Barrier Reef. Abundances and distributions of bioeroding sponges are displayed for the different reef zones during the surveys 1997/98 and 2003/04. Reef zones: RF – reef flat, s – sandy, m – mixed, p – pavement, b – branching corals, RS – reef slope. During the second survey, dead substrate available for sponge settlement was +4, +1, -10, +8 and +11% in the 5 zones, respectively (Table 1). B: Changes in the community of bioeroding sponges represented by multidimensional scaling after an analysis of similarities (MDS; ANOSIM), b – before, a – after bleaching events (5 belt transects 100 x 0.5 m).

Substrate categories were distinguished as:

i) calcium carbonate in form of dead coral, mollusk shells etc.; suitable substrate for bioeroding sponges
ii) substrate covered with live tissue (corals, soft corals, other invertebrates, dense cover of algae); unsuitable substrate for all bioeroding sponges except for *C. orientalis*, which invades such areas laterally (Schönberg and Wilkinson 2001) and *A. mucosa* that may even be able to settle on coral tissue (Rützler 1971)
iii) sand; unsuitable substrate for bioeroding sponges (except for *A. mucosa* that is able to live in a piece of calcium carbonate buried in the sand; Schönberg 2001)
iv) mud; unsuitable substrate for bioeroding sponges (except for *A. mucosa* that is able to live in a piece of calcium carbonate buried in the mud; Schönberg 2001)

Where reference samples were taken with hammer and chisel, preparations were made according to standard procedures (e.g. Schönberg 2000) and included in the reference collection of the first author. Resulting species descriptions can be accessed through other publications (Schönberg 2000; Schönberg 2001; Schönberg et al. 2006; Schönberg and Tapanila 2006; Schönberg and Beuck 2007).

The earlier study was conducted 1997/98 (Schönberg 2001), the later study 2003/04. The first survey yielded data for a putatively largely undisturbed situation. The more recent survey took place two years after two severe bleaching events, which had a significant impact at the sample site and caused severe disturbance that partly resulted in over 60% coral mortality (Berkelmans and Oliver 1999; Baird and Marshall 2002; Berkelmans et al. 2004). To date only the survival of reef builders had been surveyed in this area, but not the survival of bioeroders. The studies reported here represent an unprecedented before-and-after investigation and focused on the question whether bioeroding sponges had suffered to the same extent as corals. 'Before' data were compared with 'after' data with multidimensional scaling for community composition using analysis of similarities (MDS; ANOSIM), and for total area of bioeroding sponges per survey using a paired t-test.

Table 1. Material composition and bioeroding sponge abundances averaged over all survey transects in Little Pioneer Bay, Orpheus Island comparing the situation of 1997/98 with 2003/04. Values in parentheses are standard deviations.

Results and Discussion

Both, the 1997/98 and the 2003/04 survey on bioeroding sponge abundances on the central GBR showed that symbiotic bioeroding sponges dominated over non-symbiotic ones (most common: *Cliona orientalis* and *Cliona caesia*; Fig. 1; latter as *Pione caesia* in Schönberg 2001). Another very common sponge was *Aka mucosa* that can survive on the innermost reef flat and in the mud behind the reef crest, its body being buried in the sediments and cm-long fistules reaching into the water column. *C. orientalis* and *A. mucosa* can attack live corals, while most other bioeroding sponges can only settle on or expand into dead substrates (Rützler 1971; Schönberg 2001; Schönberg and Wilkinson 2001).

Between the first and the second survey (Fig. 1A) a clear escalation in bioeroding sponge abundances occurred, with an overall increase of total bioeroding sponge area of about 150% ($p < 0.001$, paired t-test), and a stronger prevalence of *A. mucosa* on the upper reef flat and the symbiotic bioeroding sponges on the lower reef flat and on the reef slope. For *C. orientalis*, especially the early, papillate growth form became more common, indicating that larval settlement continued unhindered or was even enhanced after the bleaching events by increased availability of suitable substrate (Table 1). Despite clear evidence of the demise of various species of corals and soft corals, the more mature, encrusting growth form of *C. orientalis* had also increased in the zone formerly inhabited by branching corals, suggesting that established colonies of this sponge did not die during the bleaching events, but spread in reef areas where most coral mortality occurred. Using multidimensional scaling, mean bioeroding sponge areas per transect and available substrate clustered separately for both surveys and differed significantly, with the cluster from the first survey more dispersed than the cluster from the second survey (Fig. 1B; ANOSIM $r = 0.804$, $p = 0.008$). This pattern indicated that sponge community composition became more homogeneous, possibly implying the occurrence of a major disturbance (Connell and Keough 1985). We ascribe this disturbance to the recent bleaching events, resulting in an increase of dead surface area available for sponge larval settlement (Table 1) and reduced space competition by other reef organisms (see also Chiappone et al. 2007).

The present study represents a localized survey, but is supported by other reports of increases in bioeroding sponge abundances (Rose and Risk 1985; Rützler 2002). If we accept that bleaching events were the cause for this shift, then we will have to expect globally increasing bioerosion rates on coral reefs. This prognosis appears even more likely when considering that many sponges may benefit from growing eutrophication and pollution (see e.g. Holmes 1997, 2000). We would like to encourage further field studies on bioeroding sponges, and preferably investigations over time.

Acknowledgements
The first author was supported by a Feodor-Lynen Fellowship from the Alexander von Humboldt Foundation, Bonn, Germany and by funding from the Australian Research Council to O. Hoegh-Guldberg. We acknowledge the friendly assistance we received from staff at the Orpheus Island Research Station. H. Cambourn, E. Cebrian, W. Loh and R. Olbrich helped during the field trips and long, long if shallow dives.

Abstract. Eco-informatics is the combination of multiple environmental datasets and modeling tools used to test ecological hypotheses and derive information. The Semantic Reef project is developing automated data processing, problem-solving and knowledge discovery systems to better understand and manage reef ecosystems. Three core tools are utilized; Semantic Web, Grid Computing and workflow based e-Research approaches, creating a platform designed to evaluate complex hypothesis queries and provide alerting for unusual events (e.g. spawning, bleaching). Remote environmental monitoring is being widely deployed to gather data in real-time. As the volume of raw data increases, bottlenecks are expected to develop in the data analysis phases - current data processing still involves human intervention and manual manipulation. Semantic Web technologies address this data deluge through using explicit descriptions, called ontologies, of the datasets and structures, making the data machine-understandable, therefore automating data integration and processing. The Semantic Reef project is focused on developing reef ontologies, which, when coupled to datasets, derives inferences from data to 'ask' the system questions for semantic correlation and analysis. Currently, the model is being extended to map dynamic data from reef-based sensor-networks into the ontology in real-time, offering a new approach to solving problems of scale across reefs.

Key words: Eco-informatics, semantic web, ontologies, coral reefs.

Introduction

With the global effects of climate change, and other major issues, eco-informatics is an emerging branch of research where new techniques, tools and infrastructure are being developed to enable far greater scope for problem solving methodologies and analytical ability for the research scientist. This new cross-discipline evolution of global collaborations, with both ecological and computer scientists, is vital in the quest for knowledge and answers when addressing such major issues as climate change.

Problems are arising, however, with the imminent influx of new data and information, appropriately dubbed 'the data deluge'. This increasing flood of data is growing exponentially with the large number of deployed, or soon to be implemented, scientific data collection instruments such as sensors, satellites, scientific experiments and simulations. Hence, as the volume of raw data increases, bottlenecks in the data processing and analysis phases are occurring because current methods still involve human intervention making it progressively more difficult for the scientist to keep up effectively.

The Semantic Reef Project aims to utilize existing coral reef databases, augmented by real time sensor output, to pose hypotheses of the disparate data. The project is a Knowledge Representation (KR) system that employs Semantic Web, scientific workflows and Grid computing technologies to resolve the problems of data integration, synthesis and discovery for coral reef ecosystems (Fig. 1). It will map static and dynamic data to a set of ecosystem ontologies, which through explicit definitions will make the information machine-understandable, enabling the computer to make intelligent inferences, decisions and/or

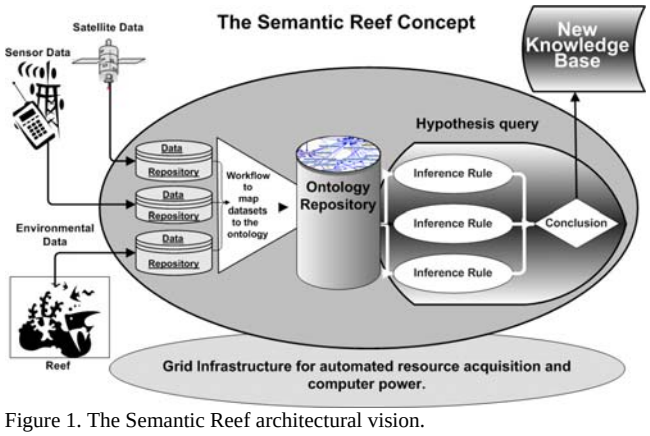

Figure 1. The Semantic Reef architectural vision.

discoveries, using logic systems such as Description Logics (DL) and propositional logic (Myers et al. 2007a).

A brief description of the Semantic Reef project, results to date and the data processing issues marine biologists are facing will be followed by a closer look at Semantic technologies, and how they may address this data deluge problem. Finally, details of the KR system and the reusable design methodologies, to semantically represent a full coral reef ecosystem, will be explained.

Background – The Semantic Reef project

The Semantic Reef project is developing a tool for use in hypothesis-driven research and problem-solving methods. It will allow for automated data processing and analysis of disparate databases and data streams through the technologies enlisted in the architecture. These technologies include Semantic Web, Grid computing and scientific workflows, which together create synergies to address particular issues in data integration. The resulting technology platform is designed to improve our capacity to generate timely warnings of environmental conditions that are conducive to climate change issues or unusual events within the coral reef environment.

At the heart of the Semantic Reef project are the Semantic Web technologies, which are an emerging area of computer science that aims to support automated processing of information. Through ontologies, which are the foundation of Semantic technologies, concepts are explicitly described, giving context and meaning to the data the computer can access. Here, a set of re-usable ontologies have been developed to describe to a computer the concept of, and the relationships within, a coral reef ecosystem.

The model is built on a Grid Computing foundation which provides the tools for secure and reliable access, sharing and management of resources, namely raw data and computational power (Foster et al. 2001). The scientific workflows are developed using the Kepler workflow software (Altintas et al. 2004), to automatically process raw data, and pass the results through the expert system.

To assess the accuracy of the architecture, validation tests were conducted. Initially, with a focus on the coral bleaching phenomena, a reverse hypothesis methodology to ground truth the system was employed and the outcome of the inference propositions were compared with actual historic bleaching events. For the validation, the stress factor most commonly associated with the bleaching event, namely elevated sea temperature (Marshall and Schuttenberg 2006), was used with the available historical data acquired through the Great Barrier Reef Marine Park Authority (GBRMPA) on the 1998 and 2002 mass bleaching events. The thermal stress indices trialed were the Sea Surface Temperature plus (SST+) and Degree Heating Days (DHDs), which are commonly used to describe thermal anomalies (Berkelmans et al. 2004; Maynard et al. 2008). Logical inference rules and DL were used to mimic these metrics then executed using the historic temperature data. The results of the automated inference were found to relate closely to those of previous research on the tolerance of corals to temperature changes, thus verifying a successful test (Myers et al. 2007b).

Since the initial validation exercise, a richer set of ontologies have been developed. The hierarchical design employs re-usable multi-scale ontologies to represent the functionality and complexity of a coral reef ecosystem making the concept computer-understandable for auto-processing objectives. The intention is to allow marine scientists, from around the globe, tools to test hypotheses and probabilities, through enlisting a semantic 'richness on demand' environment. The ontologies, ranging in complexity, describe concepts such as the composite population of the reef community, human influence contributors, bathymetry, environmental factors, among others, in computer-understandable semantics. Using this modular approach, reusability is afforded, where the knowledge being sought or the hypothesis being posed will determine the choice of which ontologies to utilize and what data is used to populate them. For example, extending the validation inference rules used for a bleaching occurrence, which are currently based solely on SST, to introduce other premises such as water quality, location, nutrient levels, salinity, etc, would be a trivial task programmatically.

The Data Deluge

Many scientific disciplines are experiencing changes in how research is being performed due to digital technology from the next generation of experiments, simulations, sensors and satellites generating a flood of valuable data for scientists to interpret (Hey and Trefethen 2003). The data is being gathered globally in differing formats and for different agendas and the bridging between all these disparate sets is the real issue that many technological developments, such as the one described here, are attempting to address.

The use of environmental sensor networks to gather data in real-time across widely distributed areas is an expanding field, detailed by projects such as the Integrated Coral Observing Network (ICON) in the USA (NOAA-ICON/CREWS 2008) and the Integrated Marine Observing System (IMOS) in Australia (IMOS 2008). Applications of new technologies and processing systems are being trialed on the Great Barrier Reef (GBR) such as the Great

Barrier Reef Oceans Observing System (GBROOS 2008). As habitat researchers deploy embedded sensor networks, strategies on capturing, organizing, and managing large amounts of streaming live data is becoming a critical issue. It is imperative the processing and analyzing of the data be effective and efficient. However, it is becoming evident that current technologies are not scalable enough to quell the imminent deluge or make proficient methods of analysis and research possible.

The data is being gathered and stored in a myriad of different repositories and although there are data mining efforts to bridge across this disparate data most are still considered stand-alone unconnected data silos. So how do we search and infer new knowledge across the breadth of available data automatically? With the main focus of data accessibility, integration and automated processing, Semantic Web technologies offer a possible solution.

Semantic Web Technologies

Semantics is the study of meaning and dates back millennia in the philosophical arena. The term 'Semantic Web' was coined by Sir Tim Berners-Lee in his original proposal to CERN to develop the World Wide Web (Berners-Lee 2000). He described the Semantic Web as being the evolution from a Web of cross platform documents to a 'Web of data', where complex decision making by the machine will be possible as the information contained within the web pages will be both human-readable and computer-understandable. Ideally, with the decrease in manual intervention, it will allow search and analysis mechanisms greater autonomy to sift through the massive amounts of knowledge and data available on the Web and automate the process of creating new knowledge.

The Ontology

At the heart of Semantic technologies is the ontology. Ontologies are documents or files that formally define the relations among terms and representing abstract or specific concepts: intentions, beliefs, objects or feelings. These descriptions contain explicit specifications, terms and relationships with formal definitions, axioms and restrictions that constrain the interpretation by the computer, thus making data computer-understandable enabling it to make intelligent decisions based on inference rules and DL (Antoniou et al. 2001). Of course, the computer does not literally 'understand' the information, but it can now manipulate the terms much more effectively in ways that are useful and meaningful to the human user, such as being more functional in cross platform environments when dealing with disparate data from diverse sources.

Modern ontologies can be engineered at differing levels of complexity, from shallow (i.e. a domain vocabulary, thesaurus, or taxonomy) to the composite category, which involves applications of logical definitions to automate conclusions, assumptions and subsumptions through classification and inferences. Creating unambiguous definitions of things, concepts and ideas assists in bridging across disparate data sets, for example, well defined synonymous relationships would allow '*Acropora formosa*' in one database schema to be easily bridged to 'stag horn coral' in another. In addition, defining homonyms by adding context affords the ability for the computer to interpret contextual information. For example, the word 'fluke', to the machine, is five characters of eight binary bits each, it has no meaning to the computer, however, associating the word with a 'part of' or an 'is a' relationship to another word, such as anchor, dolphin, fish or flatworm, adds enough contextual information so the computer can make meaningful connections automatically.

The Logic Systems

There are number of differing formal logic systems available within the scope of Semantic technologies each orthogonal to the next. The field of DL is a subset of First Order Logic (FOL) and has been used throughout history, it allows for expressing relations between concepts in a generalized fashion for reasoning with logical axioms and quantifications (Baader 2003). To give a simple example, an omnivore could be generally defined as, among other things, any animal that eats both plants and animals. Translated into the Web Ontology Language with DL (OWL-DL) (McGuinness and van Harmelen 2004) would be written as:

```
OmnivoreClass eats SOME
(PrimaryProducerClass AND
(HerbivoreClass OR CarnivoreClass))
```

Upon classifying using a reasoning engine, any instances that are defined with the property 'eats' and is linked to both a member of a plant class and animal class (e.g. an instance of the Sea_Grass class and the *Bivalvia* class respectively), will automatically be subsumed to belong to the omnivore class (e.g. all instances of the Loggerhead_Turtle class). This ability of the KR system to automate latent connections and make dynamic inferences of relations (i.e. automatically connecting the hidden dots), is imperative for modeling such an intricate multi-scaled concept as a reef ecosystem.

Propositional logic adds the ability to infer conclusions based on sets of predefined premises. The Semantic Web Rules Language (SWRL) uses 'horn-like' rules, composed as syllogisms, to produce logical conclusions (Horrocks et al. 2004), which

allow for hypothesizing over the full knowledge base. Posing hypothetical questions with known or best guess factors can allow for conclusions to be drawn by deductive and inductive inference, where observation would prove or disprove the hypothesis.

The Open World Assumption

Marine science, in general, maintains an Open World Assumption (OWA), that is, nothing is false until explicitly proven false. Traditional database implementations such as relational databases are required to maintain a Closed World Assumption (CWA), that is, everything that is known about the world exists within the boundaries of the database and its schema. This creates a mismatch between the researchers need for dynamic multi-scale complexity open to changes upon new discoveries and the current technological capabilities for flexibility.

Semantic Web languages have an OWA where it is assumed knowledge of the world is incomplete. Specifically, 'not true' is not automatically false, it is considered unknown; it assumes the extra information required has not yet been added to the knowledge base. As new discoveries are quite feasible in the marine biology domain, there is a need for flexibility allowing new knowledge and concepts to be assimilated into the system without difficulty; the OWA caters to this need (Horrocks et al. 2003).

In illustrating the differences between OWA and CWA, when describing the makeup of a particular reef the schema includes only these two statements: 'Davies Reef has *Favites*' and 'Davies Reef has *Porites*', a query of whether Davies Reef contains any *Acropora* would return false in a CWA, which would be incorrect. However, with the OWA, unless there is a statement that explicitly declares 'Davies Reef has no *Acropora*', the system will conclude there may be *Acropora*, it simply has not yet been explicitly asserted.

Building the Semantic Reef ecosystem ontologies for multi-scalability

Concepts can be modeled through ontologies in a variety of ways and varying degrees of granularity. The Engineering and design choices on what type of ontology to build is determined purely by the degree of extensibility and expressiveness required to produce the desired information or knowledge. However, the flexibility and reusability becomes more restricted, in ontological design, as complexity increases (Gomez-Perez et al. 2004).

Clearly, coral reefs are highly complex, interdependent ecosystems. It became apparent the use of a singular top-down, large ecosystem ontology would not be simple to create, implement nor maintain, as the number of variables and multi-scale relationships are immense. Therefore, a 'mix and match' bottom-up approach in the ontological design was adopted. Specifically, a range of separate ontologies were created to describe the many diverse concepts that make up a coral reef, such as, community and environmental composition, hydrodynamics, human influence and trophic layers, among others.

The current set of ontologies consist of reef and environmental taxonomies at the lowest layers, which import to heavier-weight DL ontologies for concepts such as trophic layers that require richer relational descriptions (Fig. 2). To illustrate, the reef community composition is an uncomplicated ontology, where only synonymous and hyponymous (i.e. 'same as' and 'is a') relations are defined. When populating the ontology, this method allows for a less complicated bridging mechanism across disparate databases, which may list either scientific names or common names, but not both. This and other simplified ontologies, such as one that describes and maintains temperature information, can then be ported to the heavier-weight ontologies. Separating the logical complexities from the instance data at the lower layers, makes ontological structure reusable.

'Domain task specific' ontologies lie at the highest level of granularity. It is at this level the finely detailed rules are introduced as propositions, written in SWRL, to infer conclusions from the available data within the knowledge base. For example, to hypothesize about coral bleaching on the GBR would have all lower ontologies populated with available or relevant data (e.g. salinity, chlorophyll, real-time temporal and spatial SST data, etc), then imported into a domain task GBR ontology, where inference

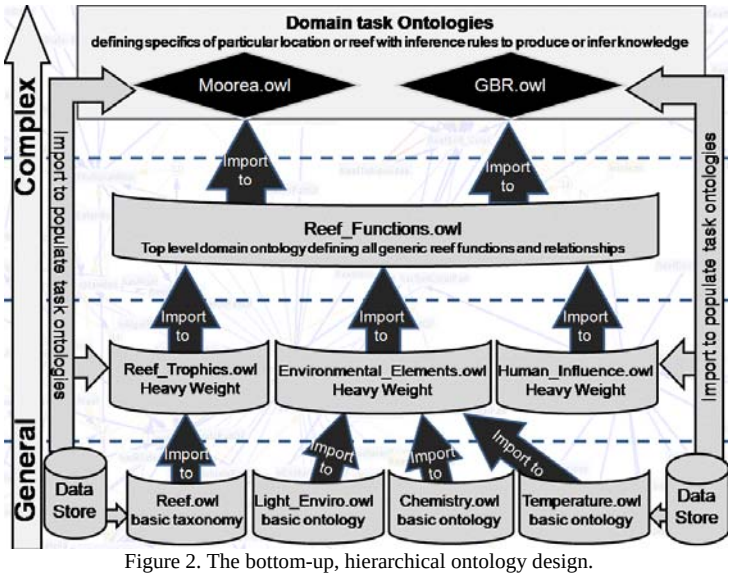

Figure 2. The bottom-up, hierarchical ontology design.

rules can be structured to infer a bleach alert. As the infrastructure is designed to be generically reusable, the same ontologies, populated with different location specific data, could be used for a different hypothesis on any reef, for example, a sensitivity analyses for coral spawning on Moorea Reef (Fig.2).

Future Works and Conclusions

We are drowning in a sea of data, which occasionally is generously referred to as 'information' and almost all of it must be interpreted by humans to be of any use. The growth and availability of new data sources and, therefore, our need to consider it in research, decision-making and planning is growing exponentially, and our systems, rather than helping with this, are predominantly contributing to the problem. Hence, the demand for automated data analysis and/or hypothesis-testing systems is becoming increasingly imperative as the escalating range of data gathering devices and instruments are deployed.

The Semantic Reef is a new approach to such data analysis and interpretation issues. The modular ontology design allows for inclusion of both scientifically known factors as well as phenomena yet to be discovered. Therefore, as user driven propositions change due to new findings, information or queries, and as new data sources become available, the open world nature of Semantic technologies will make uncomplicated additions and eliminations to the KR system possible.

Here, highly diverse backgrounds and expertise have combined effectively in collaboration to structure a semantically driven architecture to assist the marine biology domain in confronting the data deluge challenge. Currently, the processing capabilities of the Semantic Reef system are being tested to infer a coral bleach warning using satellite data from the US National Oceanic and Atmospheric Administration (NOAA 2008) and real time SST data streamed directly from the Davies Reef microwave site, part of the GBROOS project (GBROOS 2008). Further additions to the hypothesis will see the addition of other causal factors, as the data becomes available, such as chlorophyll provided by AIMS and salinity levels from IMOS.

GBROOS – An Ocean Observing System for the Great Barrier Reef

S. Bainbridge[1]

[1]Australian Institute of Marine Science, PMB 3 MC, Townsville, Queensland, 4810, Australia.

Abstract. The Great Barrier Reef Ocean Observing System (GBROOS), a geographic node of the Australian Integrated Marine Observing System (IMOS), is an observation network deployed along the Great Barrier Reef (GBR) in Northern Australia. The project aims to quantify and monitor the impact of the Coral Sea, in particular cool and warm water intrusions, on the GBR and to provide the real-time data required to understand the impact of climate change and other environmental factors on coral reef ecosystems. The project has five components. Sets of paired deep (200 m) and shallow (30-70 m) oceanographic moorings will be deployed to detect water moving onto and along the GBR from the pole-ward East Australian and the equatorial Hiri western boundary currents. Upgraded Remote Sensing capacity, coupled with underway validation data, will give large-scale information about the GBR. A set of reference moorings will provide long-term baseline data on water parameters supplemented by detailed monthly water samples. Sensor networks located at seven sites will provide real-time information about small-scale phenomena. The observational data will have significant impact on our understanding of global change, its potential impact on the physical and chemical conditions and the associated changes to the biology and structure of the GBR.

Keywords: GBR, Ocean, Observing, Sensor networks, Climate change, Great Barrier Reef

Introduction

GBROOS is an observation network that seeks to understand the influence of the Coral Sea on continental shelf ecosystems in north-east Queensland including the GBR Marine Park.

The South Equatorial Current (SEC) is the dominant flow in the Coral Sea. On reaching the Australian coast, the SEC bifurcates into northern and southern boundary currents. The northern arm is responsible for driving a clockwise gyre in the Gulf of Papua that is a nursery for tropical rock lobster; a major resource for indigenous communities in the Torres Strait. The southern arm becomes the East Australian Current (EAC), which flows down the eastern seaboard and affects coastal climate and ecosystem performance from southern Queensland to Tasmania (Ridgeway and Dunn 2003).

The SEC is dynamic on annual and decadal time scales. Variations in flow of the EAC associated with the Southern Oscillation Cycle (El-Niño/La-Niña) affect the thermal and carbonate chemistry regimes on the outer barrier reef, and the replenishment of commercial fish stocks along the eastern seaboard (Harris et al. 1988; Oke and Middleton 2001).

In the central GBR, the slope bathymetry favours intrusion of Coral Sea water onto the continental shelf and flushing of the outer Lagoon while also suppressing cross-shelf exchange. Many of these intrusions draw cool nutrient-rich water from the deeper Coral Sea onto the shelf (Andrews and Gentien 1982).

The Coral Sea has a direct impact on the water that is delivered to outer-shelf reef systems and to in-shore areas where intrusions are able to penetrate through the reef matrix. These incursions play a critical part in determining the water that forms the lagoon of the GBR (Steinberg 2007). The large scale circulation and characteristics of oceanic water influences local factors and circulation to determine the thermal and other characteristics of the water that the corals experience. In order to understand how corals respond to changes in their environment we must first measure that environment, and for the GBR, this means understanding the impact and functioning of the oceanic water processes.

Material and Methods

There are five components to GBROOS that together provide information at a range of scales from synoptic remote sensing data to fine scale sensor network data.

The remote sensing component involves the installation of an L and X band receiving station in Townsville for the collection of the older AVHRR data and new higher resolution data such as MODIS. This compliments an existing L-Band receiving station that has been operating since the mid 1980's.

To compliment the remotely sensed data a number of vessel-based systems are deployed to collect daily validation data. A radiometer mounted on a commercial ferry that transits between Shute Harbour and Hardy Reef collects radiance data to validate the AVHRR SST data. An Ocean Colour reference station is being established near Lucinda in North Queensland to validate the MODIS ocean colour data.

Underway water quality data is being collected from two AIMS research vessels (the *R.V. Cape Ferguson* and the *R.V. Solander*) and a commercial ferry operating between Gladstone and Heron Island in the southern part of the Great Barrier Reef. The instruments consist of a Sea-Bird thermo-salinograph (temperature and salinity) and a WetLabs FLNTU (chlorophyll and turbidity) as well as position from the vessel GPS. The data is downloaded nightly and will be used to validate other data, such as remote sensing data, and to build up a long-term data series. For the commercial ferry this will be for the same transect, for the research vessels this will be for their area of operation over northern Australia.

As part of the larger IMOS project a number of identical reference moorings are being located around Australia to provide equivalent long-term records of basic water parameters. GBROOS is responsible for two of these moorings; one off Townsville in North Queensland and one near Darwin in the Northern Territory. The instruments deployed include a near-surface (around 10 m depth) and near-bottom (around 5 m from the bottom) WetLabs WQM (temperature, salinity, depth, turbidity, chlorophyll), a series of temperature sensors (Sea-Bird SBE39's) along the mooring wire, a surface buoy mounted weather station (Vaisala WXT-510/520 – air temperature, wind speed and direction, relative humidity, rain duration and amount, barometric pressure) and waves and currents (via a bottom mounted Nortek AWAC). The design is shown in Fig. 1.

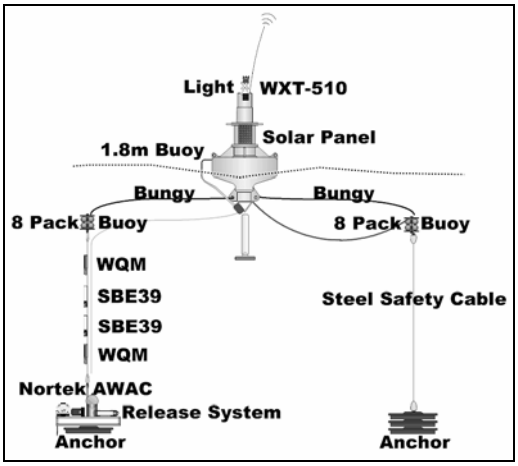

Figure 1: The basic design of the Reference Station moorings.

Water samples will be collected from the Reference Stations monthly. The parameters investigated include hydrochemistry (nitrate, nitrite, phosphate, etc), carbonate chemistry, suspended matter, zooplankton, phytoplankton pigments, as well as a CTD cast and validation samples for the instrument data.

The fourth component of GBROOS is the GBR Mooring Array. This consists of four pairs of moorings located along the GBR with one of the pair located on the continental slope in relatively deep water (70-200 m) and the other of the pair located on the continental shelf in shallower water (30-70 m).

The design looks to detect the movement of oceanic water up the continental slope and onto the shelf and so give information about upwelling events and about the strength and direction of the oceanic currents as they impinge on the reef matrix. The locations of the moorings and the main current flows, as measured by surface flows, are shown in Fig. 2.

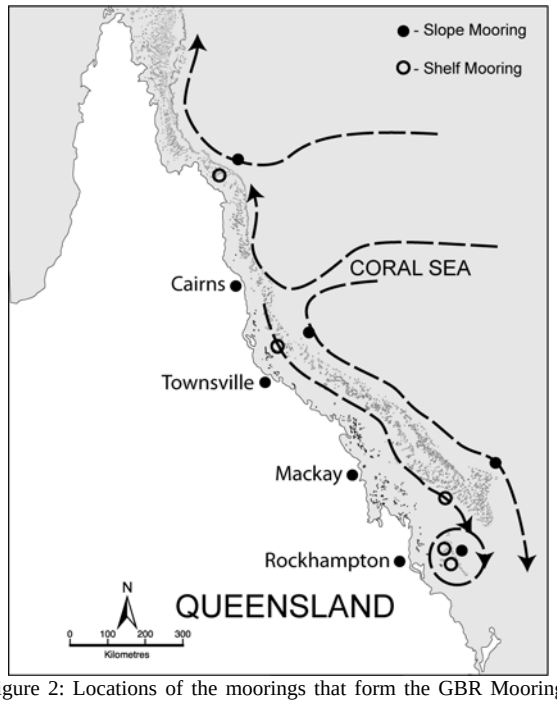

Figure 2: Locations of the moorings that form the GBR Mooring Array, slope moorings are shown as solid markers, shelf moorings as open markers. The major currents are shown as dashed lines based on current surface flows (from Steinberg 2007).

The basic current flows (Steinberg 2007) show the main south equatorial current impinging on the GBR in the Cairns area with one flow going north as the Hiri current and one going south to form the East Australian Current. The southward flow includes components that go down the outside of the reef matrix and those that flow through the larger GBR lagoon. The two flows meet in the southern part of the GBR where a complex series of eddies occurs before the main southward flow becomes coherent.

The pair of moorings off Townsville looks to measure water intruding from the deeper slope onto the shelf or reef matrix so supplying coastal reefs with oceanic water. In this area the reef matrix is open and so water is able to move up and across the shelf. The moorings around Lizard Island are designed to measure the northward current flow outside the reef matrix and the inflow of that water through the ribbon reefs into the reef matrix. The moorings south of Mackay are positioned to measure the southward current flow outside the reef matrix via the deep water mooring and through the main reef lagoon using the inshore mooring.

Around Heron and One Tree Islands three moorings have been deployed, two shelf and one slope, to capture the complex nature of the currents in this area.

The deeper moorings do not have a surface float and so log their data, the shallower shelf moorings will be converted to a surface buoy and will have real-time communications installed. This will allow for summary real-time data to be communicated; the instruments will continue to log the full data set which is retrieved on servicing. The moorings are serviced every six months.

The moorings typically contain a sub-surface float at 10 m, a series of Sea-Bird SBE39 temperature and pressure sensors down the mooring giving surface (10 m), middle and bottom measurements with five minute sampling. These are complimented by two WetLabs WQM's deployed to give upper and lower water column temperature, salinity, turbidity and fluorescence also sampling at five minutes. Currents are measured with a near-bottom mounted Acoustic Doppler Current Profiler (ADCP). For shallow moorings (< 100 m) an RDI 300kHz ADCP is deployed with a sampling of 30 minutes at 25 four-metre 'bins' or intervals, for deeper moorings a Nortek 600kHz ADCP is used with 50 four-metre bins. Some moorings have a Nortek AWAC for waves and currents. At the start and end of each deployment a CTD cast is done with a Sea-Bird SBE19+ to give validation data for the deployed instruments as well as giving start and end profiles.

The final component is the wireless sensor network. Sensor networks will be deployed at seven sites, four island research stations (Heron and One Tree Islands in the southern GBR, Orpheus Island in the central GBR and Lizard Island in the northern GBR) and three reefs (Davies, Rib and Myrmidon Reefs, all in the central GBR). The locations are shown in Fig. 3.

At each site a high speed data link is installed using microwave links or 3G phone technologies. An on-water wireless network is then created using a series of network repeater poles located around the reef and a 900 MHz spread-spectrum radio system.

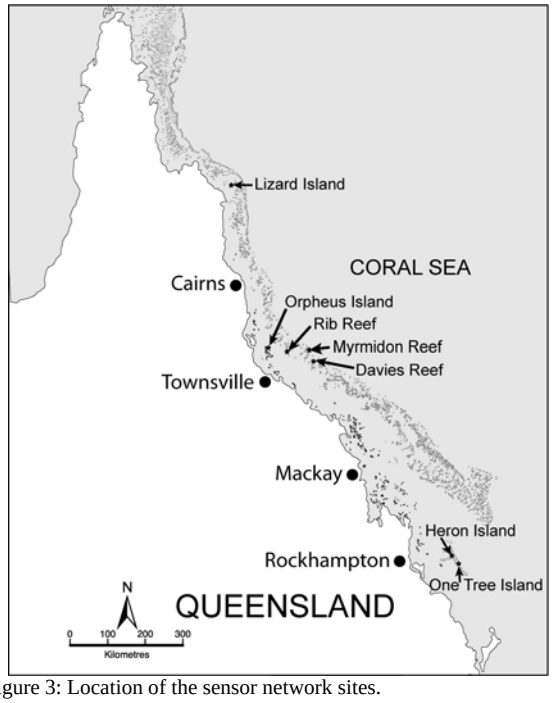

Figure 3: Location of the sensor network sites.

Into this network are located the sensor floats onto which the actual sensors are attached. The floats contain a logger and radio that transmit the data back to the base station and then, via the data link, back to AIMS. The data is relayed in real-time and made available via streaming sensor middleware.

The design allows for areas to be intensively wired up and monitored, much of the equipment is relocatable and can be deployed around individual coral heads and bommies giving real time information about the conditions around the corals themselves. The initial sensors include temperature, salinity and depth but the infrastructure is suitable for other sensors, such as video, partial pressure of CO_2 (pCO_2) and photosynthetically active radiation (PAR). The involvement of the island research stations that form the Tropical Marine Network (TMN) allows for cleaning and maintenance of equipment and the specific deployment of equipment for short-term experiments.

Affiliated with the GBROOS Node is the Australia Coastal Ocean Radar Network (ACORN) facility that is installing WERA based HF coastal radar systems. A system will be based in the southern GBR to give coverage over most of the southern GBR area including the moorings and sensor network sites in the Heron Island area. The coastal radar will therefore provide additional information about waves and surface currents in this area.

All of the data will be made freely available as soon as possible via a dedicated GBROOS data web site or via the IMOS web site (www.imos.org.au).

Results

The project has been operational since mid 2007 with significant deployments already undertaken and the remaining due to be completed by 2009. The first data from most of the components is now being collected and the data management systems are being built to make the data available.

The remote sensing station was commissioned in May 2008 and is sending data to the Bureau of Meteorology for inclusion in their processed products along with some of the vessel based validation data.

The underway systems have been installed on two research vessels with the commercial ferry to be completed by mid-2009. Some initial data has been collected; this is currently being processed and will be available from the final data web site.

The Townsville reference mooring has been deployed in a reduced mode without the surface float and so the data is currently being logged. The station will go to real time in the first half of 2009. The Darwin station is due to be installed in mid-2009 as a real-time buoy with the data available soon after.

The mooring array has been operational since mid 2007 with service/data download visits being performed every six months. The initial data is being analysed and the data management systems are being built so that this data can be made available on the web. There has been a delay in doing this as there is a need to first develop some underlying data standards within the IMOS community and this is taking time.

The initial data from the southern GBR moorings shows periods of distinct stratification of the water column inter-dispersed with mixing events that mix the water down to 40 or more metres. This data is being analysed against the remote sensing and coastal radar data to identify the source and cause of these mixing events and to link these into movements of the currents in this area and events such as upwelling.

Three of the seven sensor network sites have been deployed; these are Heron and One Tree Islands in the southern GBR and Davies Reef in the central GBR. The deployments at One Tree Island consist of three sensor poles, one in each of the smaller lagoons within the main One Tree Island lagoon. The sensor poles have a series of thermistors going from reef flat down into the deeper water of the lagoon. At Heron Island five sensor floats have been deployed around the lagoon each with a surface thermistor, as well the six network relay poles have a single bottom thermistor attached. At Davies Reef the sensors currently deployed include a weather station and a number of sensor floats with surface thermistors. Additional sensors will be added to the existing deployments by mid 2009, these will include depth (pressure) and salinity.

Initial results from One Tree Island Lagoon from the sensor network component for late September 2008 (see Fig. 4) show a series of daily cycles in temperature with increasing temperatures as the days go by and then a series of events that re-set the temperatures. This may be caused by periodic mixing of colder oceanic water into the relatively protected lagoon or by a series of cold-water events pushing colder water into the lagoon. This pattern is also seen at nearby Heron Island indicating that larger scale processes may be at work such as cold water moving onto the reef or through weather events that reduce the surface temperature of the water. A reef-based weather station is due to be installed that may shed some light on the cause of these events. This result shows that there are processes operating at a weekly scale that have the ability to alter water temperatures by four to five degrees in rapid periods of time.

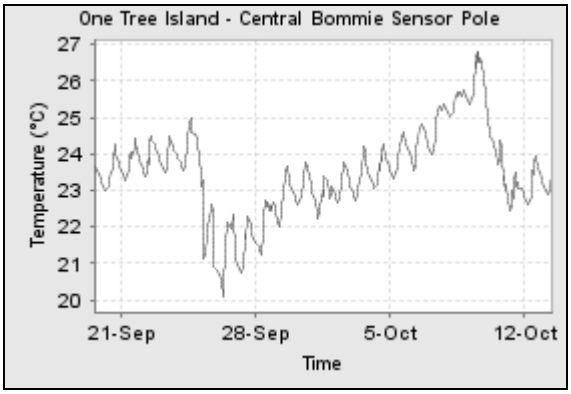

Figure 4. Plot of temperature over time for the bottom (lagoonal) sensor on the sensor pole located in Central Bommie, One Tree Island lagoon, southern Great Barrier Reef for late September 2008.

The project is committing resources to develop data management systems for all of the data being collected. The systems include data archiving of files, quality control of the data, production of metadata (to ISO 19115 standard) and the ingestion of data into a common database schema.

The work includes the development of service based data access routines where access to data and data products (such as Google Earth files, GIS files) is done automatically via user or client submitted URL's. This will allow web sites to be built around the data and for other users to tap into the data using their client of choice, from Matlab, Excel to simple text editors.

For the mooring data the project will help develop a 'toolbox' of routines for processing the raw instrument data as well as an agreed to final file format. With the sensor network data the project is deploying specialised streaming data middle-ware (such as the Data Turbine software) to give users access to real-time data with minimal or no delay.

Discussion

Coral reefs face a range of threats and globally the outlook for coral reef systems is not good. Wilkinson (2004) estimates that some 20% of reefs globally have been effectively destroyed with another 24% under immediate threat and a further 26% under longer term threat. Issues such as climate change are more insidious as the impacts cannot always be dealt with by local management activities and so even reefs that are well managed can be impacted. This disconnect between the impacts that are causing declines in coral reef systems and the local management of the reefs represents a dramatic new turn for the conservation and sustainability of coral reef systems worldwide.

The need is to better understand how each system is exposed to, and impacted upon, the ocean systems that provide much of the water that feeds into the reef and how changes in currents, in upwelling and circulation, impact the long term sustainability of these reefs. Critical to this understanding is the ability to monitor these systems and in particular the interactions with the main oceanic water systems. Observing systems such as GBROOS are designed to help understand and monitor these processes.

GBROOS provides data at range of scales; from synoptic remote sensed imagery of sea surface temperature and ocean colour to underway sampling that gives surface water information across regular transects to the fixed mooring sites that provide long term detailed profile data at key locations. The sensor networks provide re-locatable fine scale information at the level of individual coral heads. Being able to link data from the scale of tens of kilometres down to tens of centimetres is unique and hopefully will provide the connectivity information required to fully understand the impact of large scale oceanic events on the microclimate and biological responses of individual corals.

Future work will look at the linkages between the various observing components and in particular to investigate the linkage between large scale ocean processes and small scale within reef processes and subsequent biological responses. A series of experiments are planned for 2009/10 at Heron and One Tree Islands to develop and validate models that better express the linkage between processes operating at differing scales.

In the northern sites the work will focus on tying biological processes, such as spawning, into the physical parameters and to again develop models of behaviour and responses that are driven or impacted by physical water conditions. The aim is to better understand these processes and the potential and real impacts of change on the fundamental biological systems.

Under the governance model of the project all data will be made freely available as soon as possible with much of it being in real-time. The infrastructure of moorings, communications systems, data management and logistical support will be made available to the marine science community via a competitive bidding system managed by IMOS. This means that the GBROOS data and infrastructure are open to all and that as such GBROOS belongs to the science community not to a few agencies.

GBROOS looks to provide the data, through a range of real-time and delayed mode data streams that will facilitate the development of new models and understandings of how oceanic processes impact and drive coral reef systems and how changes in these large-scale systems are related to smaller scale events such as the bleaching of an individual coral. Being able to measure the entire thermal history of a coral head will give much better understanding as to why some corals bleach and others don't.

Observing systems will not replace divers or field work but as they are able to provide real-time, long-term and *in-situ* data they are an important part of understanding how these systems function and how the biological responses observed in the field link to the fundamental oceanic forces that drive reef systems. GBROOS is a first step in a systematic attempt to provide the information required to support modelling and visualisation work and to support a range of fundamental and applied science.

Acknowledgement

GBROOS is a geographic node of the Australian Integrated Marine Observing System (IMOS) project and it is funded under the Australian Federal Government's National Collaborative Research Infrastructure Strategy (NCRIS) and by the Queensland State Government. The author would like to thank Mr. Craig Steinberg and Dr. Miles Furnas for input into this paper as well as the whole GBROOS team for their work in making the project happen.

Abstract. Assessment of coral reef ecosystems implies the acquisition of precision data and observations appropriate for answering questions about the response of multiple organisms to physical and other environmental stimuli. At the National Oceanic and Atmospheric Administration's Atlantic Oceanographic and Meteorological Laboratory, we model marine organismal response to the environment in terms of a Stimulus/Response Index (S/RI). S/RI is computed using an approach called heuristic programming, from parameters bounded in subjective terms, which are defined numerically by comparing historical data with expert opinion, so as to match research and our understanding of the process in question. The modeled organismal response is called an ecological forecast, or ecoforecast, and relative possibility and intensity of the response is reflected in a rising S/RI. We have had success to date in modeling coral bleaching response to high sea temperatures plus high irradiance and other parameters. The approach requires, a) highly robust instrumentation (in situ, satellite, or other) deployed for long periods and producing high quality data in near real-time, b) a basic understanding of the process, behavior and/or physiology being modeled, and, c) a knowledge of approximate threshold levels for single or synergistically acting environmental parameters that elicit the phenomenon in question.

Key words: coral reef · artificial intelligence · bleaching/stress model · data integration · NOAA

Introduction

As stewards of the marine environment in US territorial waters, the National Oceanic and Atmospheric Administration (NOAA) must continually strive to understand how marine ecosystems respond to environmental and anthropogenic change so as to protect its fisheries resources, shorelines, and areas of high biodiversity and intrinsic beauty, such as the many square miles of coral reefs, sea grass and kelp meadows, and other ecosystems. Because of the accumulating stresses through global warming, toxic and eutrophying effluent, and opportunistic and introduced invasive species, detecting early change in the environment becomes not just desirable but critical to the well-being of ecosystems and humans alike, especially when remedial action can only be taken less expensively at an early stage. At the Atlantic Oceanographic and Meteorological Laboratory (AOML), the Integrated Coral Observing Network (ICON) has since 1998 (Hendee et al. 1998) improved upon a series of artificial intelligence techniques to produce near real-time data-driven models of how organisms or events are influenced by meteorological and oceanographic stimuli acting singly and synergistically. These models, when validated and used to provide decision support for Marine Protected Area (MPA) managers, or to add to researchers' knowledge of stimulus by the environment (as well as response by organisms or ecosystems), are called ecological forecasts or "ecoforecasts," and are more formally defined as predicting "the impacts of physical, chemical, biological, and human-induced change on ecosystems and their components" (CENR 2001; Brandt et al. 2006).

Thus, the ICON program has developed a numerical measure of the response by organisms and ecosystems to these impacts called a Stimulus/Response Index, or S/RI. The S/RI can also serve double-duty by informing station maintainers and AOML researchers of any drifting or otherwise errant environmental data when those values are found to be outside acceptable ranges as defined by ecoforecast models.

Measuring the Environment

Sensors in the marine environment have to be routinely maintained and calibrated to ensure quality data or the whole exercise of producing ecoforecasts would be fruitless. Stations we at AOML produce for deployment are called Coral Reef Early Warning System (CREWS) stations, named after the early ecoforecasting software developed by Hendee et al. (1998), and later improved (Hendee et al. 2006; 2007).

CREWS stations have been deployed near Lee Stocking Island, Bahamas; Salt River Bay, St. Croix, US Virgin Islands (USVI); La Parguera, Puerto Rico; and Discovery Bay, Jamaica; with new stations over the next two years currently being planned for Brewer's Bay, St. Thomas, USVI; Little Cayman, Cayman Islands; Managaha Bay, Saipan, Commonwealth of the Northern Marianna Islands; and Kenting National Park, Taiwan. These stations produce meteorological and oceanographic data: wind speed and direction, barometric pressure, precipitation, light (above and below water), sea temperature, salinity and tide height. Research specific instruments have also been deployed: partial pressure of CO_2 and pulse amplitude modulating (PAM) fluorometry. Realizing the goal of maintained and calibrated instruments requires participation of field scientists and technicians, who also provide necessary support by validating ecoforecasts produced from AOML. The instrumental architecture (data acquisition and transmission) for CREWS stations has been elaborated elsewhere (Jankulak et al. in press).

The ICON program also produces ecoforecasts from data received from other in situ networks: the SEAKEYS Network of stations in the Florida Keys (Ogden et al. 1994); NOAA AOML's South Florida Ecosystem Research and Monitoring Program stations also in the Keys (SFP 2008); NOAA's National Marine Fisheries Service (NMFS) network of buoys maintained by the Coral Reef Ecosystem Division (Hawaii) in the Pacific; and the Australian Institute of Marine Science's Weather Network of eight stations on the Great Barrier Reef (Berkelmans et al. 2002) Most of these stations are well maintained, but some are so remote it is difficult to do this in a timely way.

On the assumption that sea-surface data derived from satellites are relatively good, considering their well studied and proven algorithms, data are also received from latitude/longitude pairs representing target sites for multi-parameter data collection, and called "virtual stations" (Hendee et al. 2008). Satellite data have been collected from 111 virtual and in situ station sites to date, from all three major oceans, with more planned for the future. Ecoforecasts produced from these data are always compared with in situ stations when there are some nearby, but that is not always the case. In all cases, field validation of ecoforecasts is necessary to improve or correct them.

Finally, there is one other source of data for ecoforecasting at Molasses Reef and nearby sites in the Florida Keys National Marine Sanctuary (FKNMS): Wellen Radar (Shay et al. 2002). This source of data continuously tracks surface currents, which are useful in onshore flux (Gramer et al. 2008) and larval drift ecoforecasts (L. Gramer, unpublished).

Information Architecture

Fig. 1 displays the flow of satellite and other data from a site, through a data clearing hub, and finally back to AOML for posting to a Web page which displays the most recently transmitted Web data, as well as any ecoforecasts operational for the day.

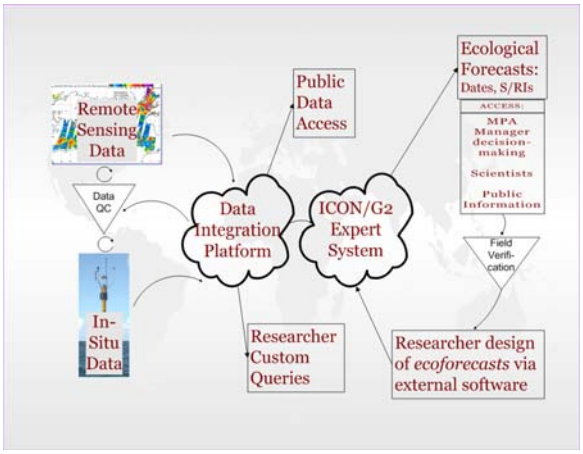

Figure 1. ICON information architecture.

Reducing Environmental Complexity

The CREWS approach to ecoforecasting seeks to reduce the extreme complexity of modeling the contributions of multiple environmental factors on eliciting behavioral and ecosystem response. Organisms respond rarely to one environmental factor; rather, they respond to a complex and often synergistic combination of factors, for instance temperature and light. One of the most complex concepts to study and understand is how the physiology of an organism that responds to, say, sea temperature and light, responds differently to a range of values for each parameter, but in combination. For instance, consider reaction to a high sea temperature and low irradiance value vs. a high sea temperature and a high irradiance value. Ideally, one would construct an index of response to an arbitrarily fine series of gradations of each of these parameters (e.g. for sea temperature, 29.01, 29.08, 29.11, etc.) in various combinations. Obviously, the number of combinations and permutations for more than one parameter quickly becomes very large. What we have done is to adopt a heuristic modeling approach. In computer science, a heuristic is "a technique designed to solve a problem that ignores whether the solution can be proven to be correct, but which usually produces a good solution or solves a simpler problem that contains or intersects with the solution of the more complex problem" (Wikipedia entry: "Heuristic" 2008). Utilizing an expert system tool called G2 (Gensym, Inc.) we use subjective terms to

describe data levels and times of day, then use those terms in "production rules" (basically, if/then constructs) to model cause and effect scenarios. To do this, we first subdivide the continua of each parameter into discrete subjective levels ("bins"), based on what historical data show are minima and maxima, and according to what researchers and users of data consider appropriate. For instance, in the open ocean, salinity readings of 34-36 psu would be considered "average" or normal, while a reading of 23 psu would be considered "unbelievably low." Table 1 lists the subjective terms we use for levels of many sensor data, along with the abbreviations utilized within the software.

Table 1.CREWS/G2 subjective data ranges.

Abbrev	Description
ul	unbelievably low
dl	drastically low
vl	very low
lo	low
sl	somewhat low
av	average
sh	somewhat high
hi	high
vh	very high
dh	drastically high
uh	unbelievably high

Table 2.
CREWS/G2 subjective daily periods.

Abbrev	Period	GMT Time	Local (@5 hrs)
(Basic Periods)			
midn	midnight	0300 - 0600	2200 - 0100
pdaw	pre-dawn	0600 - 0900	0100 - 0400
dawn	dawn	0900 - 1200	0400 - 0700
morn	morning	1200 - 1500	0700 - 1000
midd	mid-day	1500 - 1800	1000 - 1300
psun	pre-sunset	1800 - 2100	1300 - 1600
suns	sunset	2100 - 2400	1600 - 1900
even	evening	0000 - 0300	1900 - 2200
(Large Groupings)			
all	all-day	0300 - 0300	2200 - 2200
dayl	daylight-hours	0900 - 2400	0400 - 1900
nite	night-hours	0000 - 0900	1900 - 0400
dayb	dawn-morning	0900 - 1500	0400 - 1000
aftn	afternoon	1800 - 2400	1300 - 1900

Naturally, data change with time, and so does the response of an ecosystem or an organism. Table 2 shows various subjective assignments for periods of the day, following the same sort of logic as for data ranges. An additional advantage of this approach is that organisms most often are active at periods we can more easily identify with. For instance, a nocturnal animal is active during "night-hours," a diurnal animal during "daylight-hours," and a crepuscular animal during "dawn" or "sunset," and so on. This helps in the descriptive phrasing of our final ecoforecast product.

Calculating the Stimulus/Response Index

The final pre-processing of data before their utilization in an ecoforecast model is the assignment of "points" to reflect the duration of the received value at the subject level and for the subjective time of day. The points accrue to a relatively simple indexing method which assigns one point to each hour that the parameter remains in one of the subjective daily periods (Table 2), multiplied by the subjective data range (Table 1), with the latter being the key determinate of the degree of stimulus or "stress." Thus, values near "average" values are treated with a multiplier of 1, while the "very low" and "very high" designations use 2, and the "drastic" levels a multiplier of 2.5.

A decision table is a complex if/then statement which allows the knowledge engineer (a person who constructs expert systems) to weigh different input levels in the decision making process. Fig. 2 shows the use of a decision table to explain our approach in an example of a coral bleaching model, and shows how the stimulus/response index is formulated.

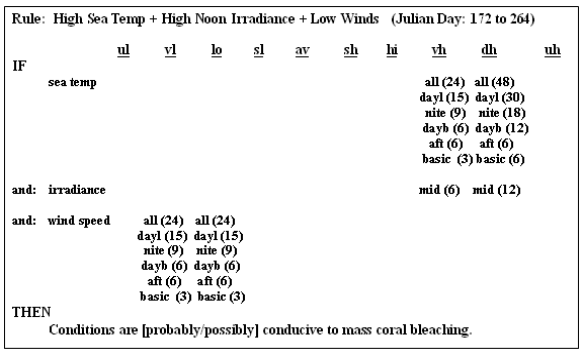

Figure 2. A decision table for coral bleaching, modeling input of sea temperature, irradiance and low winds as parameters of stress. Refer to Tables 1 and 2 as reference to the use of the abbreviations (e.g. ul, lo, dayl, basic, etc.).

To facilitate understanding, the figure may first be interpreted in a simple fashion thus: if sea temperature is high, and irradiance is high, and wind speed is low, then conditions are likely conducive to mass coral bleaching. However, the use of our point (index) system is to assign points for the duration and time of day. Therefore, the most extreme limits of stimulus (or stress) are assigned a point level of 2X or even 2.5X the number of hours of duration. So, though a 24 hour duration of "high" sea temperature would accumulate 24 points, one that is "very-high" would accumulate 48 points, and a "drastically-high" duration rates 60 points. This point system is

assigned to reflect the rarity of the "drastic" levels for each particular parameter. In the end calculation, the stimulus (or, in this case, stress) points are added up for each of the conducive parameters (e.g. sea temperature, light, winds) to arrive at a Stimulus/Response Index (S/RI).

In summary, utilizing this approach, the data process, from acquisition at the sensor to preparation of the data for a heuristic model challenge, is:

- Data are received as hourly averages from the collection site and "tagged" as to the appropriate parameter (e.g. "sea-temp").
- Data are categorized as to one of the subjective levels, as in Table 1.
- Depending upon what time of day the data are collected, they are further categorized according to Table 2 into one of the Basic Periods (three hours in length each).
- If the subjectively categorized data continues in that range beyond its originally assigned three hour period, it is further re-categorized according to the next larger period as appropriate, up to possibly "all-day."
- If the data persist at a level of stimulus (or stress) qualitatively beyond the basic threshold, they are assigned a multiplier great than unity to indicate numerically the greater stress.
- Indices from all the stimuli are added to come up with a final S/RI value, which indicates the relative intensity of the modeled response, and the relative likelihood of any response of the modeled type, to the environment at the time it is monitored.

Ecological Forecasting

Once the number of points is assigned in a heuristic model, an assessment is made as to whether those points reach a threshold level for reporting as an ecoforecast, either via an email message or Web posting to decision makers, researchers, field technicians or the knowledge engineers. Once these ecoforecasts are received, then the desirable outcome is for the field personnel (technicians maintaining a station, researchers, interested public, etc.) to give timely feedback as to whether the ecoforecast was correct as to the outcome. If it is was not correct, feedback to the knowledge engineers allows further fine-tuning of the model until, through time, it becomes a reliable ecoforecast for decision makers.

There are now many types of ecoforecasts produced as part of the ICON project, accessible via the project's Web presence (ICON 2008) which provides both hourly data from various sources at coral reef areas around the world, and ecological forecasts produced from those data. The structure of the ecoforecasts reflects one of the hallmarks of a true expert system, namely, that results are explained (i.e. "because") so that those who use the output can follow the reasoning and agree or not, and thus give feedback to the knowledge engineer so that proper refinement of the rules can take place. Figs. 3 and 4 show this approach and illustrate a current experimental coral bleaching ecoforecast being produced at Salt River Bay, St. Croix in the U.S. Virgin Islands.

Results

Early in the history of the CREWS software, the ecoforecasts were called "alerts" and were produced for the SEAKEYS Network (e.g. Hendee et al. 2001), the AIMS stations on the Great Barrier Reef (Berkelmans et al. 2002; Hendee and Berkelmans 2003), and in St. Croix (Manzello et al. 2006). With the current addition of more complex coral bleaching models reproduced at over one hundred sites around the world, as well as new types of ecoforecasts, it is now important to gain more feedback from researchers and collaborators in the field to validate and utilize them for decision support for MPA managers, and to help researchers understand how coral reef ecosystems respond to a changing climate.

```
Ecoforecast Rule #4: Coral-Bleaching-Itlw
  Description: Mass coral bleaching (high in-situ sea temperature + high light + low wind)
  This rule will produce a forecast *IF* . . .
      'Photosynthetically Active Radiation At Ocean Surface (parsurf)' has any of these values:
           High Very-High Drastic-High
      (Within any of these 3-hour or longer periods: Mid-Day Pre-Sunset Daylight-Hours Afternoon All-Day)
  AND . . .
      'Hourly Average Wind Speed (windsp)' has any of these values:
           Drastic-Low Very-Low Low
      (Within any of these 3-hour or longer periods: Morning Mid-Day Pre-Sunset Daylight-Hours Dawn-Morning Afternoon All-Day)
  AND . . .
      'Depth-Averaged Sea Temperature (seandbc)' has any of these values:
           High Very-High Drastic-High
      (Either throughout the day, or during any 3-hour or longer subperiod thereof.)
```

Figure 3. Representation of the decision reasoning on the Web site for a coral bleaching ecoforecast, considering high sea temperature, high irradiance and low winds.

Ecological forecast: 'Mass bleaching', for 2005-Sept-28, Salt River, St. Croix, US Virgin Islands
Model rule: 'Mass coral bleaching (high in-situ sea temp + high light + low wind)'
Stimulus/Response Index (S/RI) = 9, because:
Photosynthetically active radiation at ocean surface (PARsurf) was drastic HIGH (1827) during period Mid-Day
Hourly averaged wind speed (Windsp) was LOW (1.8) during period Morning
Sea temp at 1 m (SeaT1m) was HIGH (30.7) during period Pre-Sunset

Figure 4. Coral bleaching ecoforecast output, considering high sea temperature, high irradiance and low winds.

Autonomous Underwater Vehicles resurvey Bonaire: a new tool for coral reef management

M.R. Patterson, N.J. Relles

Virginia Inst. of Marine Science, College of William & Mary, PO Box 1346, Gloucester Point, VA 23062 USA

Abstract. Bonaire's reefs are among the most pristine in the Caribbean. Creation of the Bonaire National Marine Park in 1979 set an important precedent for Marine Protected Areas. Van Duyl (1985) published an underwater atlas of the bottom type and benthic community to a depth of 10 m, but there have been few surveys of the deeper (>65 m) reef. In 2008, Bonaire's reefs were remapped using three Autonomous Underwater Vehicles (AUVs), Nitrox, and Trimix SCUBA. The AUVs carried high frequency side scan and multibeam sonar, cameras, and water column sensors (CTD, pH, dissolved oxygen). Divers ground-truthed AUV data on bottom-type and biota present. AUVs were used because they can survey deeper, cover more area over shorter time periods, and simultaneously collect multiple datasets compared to surveys by ship or SCUBA. A preliminary examination of expedition data shows higher diversity (H') and coral percent cover as one proceeds from south to north. The AUVs successfully mapped the bathymetry, and collected data on bottom type, fishes, coral cover and community type at locations along the entire leeward coastline. Our work shows the potential for AUVs working in conjunction with divers to provide a new tool for reef assessment at the landscape level.

Key words: Autonomous Underwater Vehicle (AUV), Bonaire, multibeam sonar, side scan sonar, reef atlas

Introduction

Bonaire (Fig. 1A), Netherlands Antilles, is arguably among the most pristine coral reef environment in the Caribbean (Steneck and McClanahan 2004). Percent coral cover is the highest and percent algal cover the lowest compared to other Caribbean reefs (Kramer 2003) and thus it represents a baseline *sensu* Jackson (2001), with herbivory implicated in its health (den Haan et al. 2008). Bonaire's economy depends mainly on tourism with almost 30,000 SCUBA divers entering its waters in 2006 (DEZA 2006). Bonaire's reefs are among the best protected in the Caribbean with no collections of any kind allowed, with the exception of a hook and line fishery. The Bonaire Marine Park Authority oversees the administration and protection of this unique underwater resource with help from STINAPA (Stichting Nationale Parken) Bonaire, a not-for-profit foundation. Although the shallow environment near Bonaire has been extensively visited by tourists and scientists, little to no survey work has been conducted on the deeper reef (60-100 m) on into deeper water (100-300 m) (R de Leon, STINAPA, pers comm.). A recent meeting of the International Coral Reef Initiative, an effort of the United Nations Environmental Program, identified mapping of the reefs of Bonaire as a top priority (ICRI 2005).

Bonaire's reefs were extensively mapped in the early 1980s by van Duyl (1985). The resulting atlas (Fig. 1B) was compiled from high-resolution aerial photography, ground-truthed by extensive SCUBA diving. It provides a snapshot of reef cover, substrate type, and geomorphology around the time that full protection for Bonaire's waters was enacted. Long-term monitoring of Bonaire and Curaçao's reefs has been ongoing at specific locations since the 1970s (Bak 1977). Bak et al. (2005) analyzed a 30-year time series of permanent quadrats and found that while there has been some degradation of reefs in Bonaire in shallow water, corals deeper on the reef have remained at similar population levels over several decades. However, a large scale synoptic mapping effort of the scale of van Duyl (1985) has not been attempted.

AUVs are free-swimming robots that act as taxicabs for sensors. They can cover many km per day in close proximity to the seabed, providing enhanced resolution for multibeam (bathymetric) and side scan imaging sonars. AUVs can simultaneously acquire video imagery and water quality data (Patterson and Sias 1998; Hayes et al. 2007). They can also use advanced pattern recognition techniques to classify water column targets in the nekton seen on side scan or multibeam sonar down to the species level (Patterson et al. 2007). Diver video survey strategies (e.g. Aronson et al. 1994) can thus be complemented by AUVs, as AUVs can dive deeper and longer than humans, and gather more data types concurrently.

The goals of our expedition were to (1) test the efficacy of using AUV technology to conduct

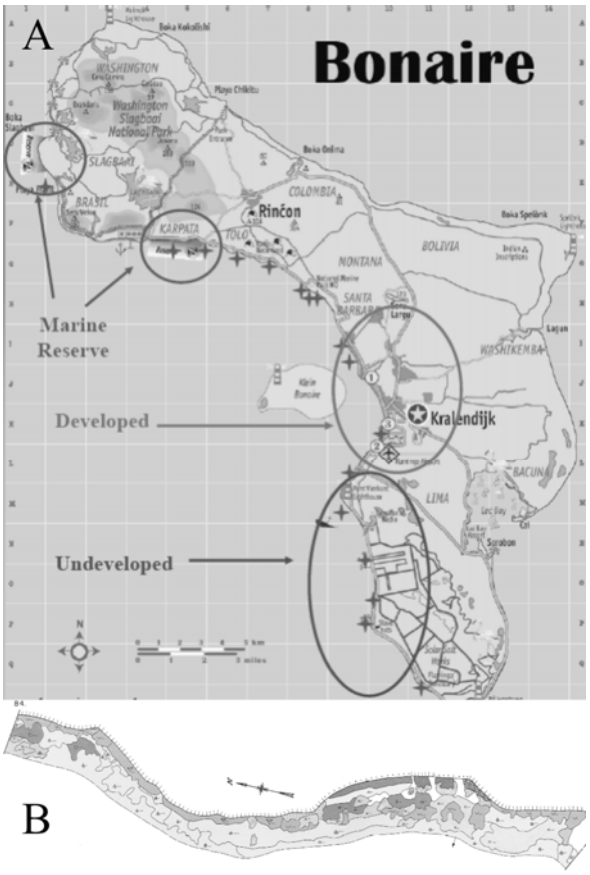

Figure 1: A. Areas targeted for diver and AUV surveys per recommendations of Bonaire government officials. Crosses represent locations where shore-perpendicular diver transects and AUV operations occurred. B. Example of a map created by van Duyl (1985). Eight community types from a set of 22 defined for Bonaire are represented in this view of the coast near Slagbaai.

bathymetric and side scan sonar surveys and video mapping in a coral reef setting, (2) concurrently characterize the physical and chemical oceanography, and (3) ground-truth the AUV data using diver surveys both shallow (Nitrox) and deep (Trimix). The long-term goal is to compare our maps with the previous survey of van Duyl (1985) to discern trends in the status of Bonaire's reefs.

Materials and Methods

Three AUVs (Fig. 2) were deployed from small boats or from shore at or near the locations shown (Fig. 1A). AUV payloads and characteristics are shown in Table 1. AUVs were operated in terrain-following and depth-holding mode. Each AUV was operated by a team of two to three people. Each of the Gavia AUVs logged about 120 dives ranging in length from 10 min to 2 hrs and depths from 2 to 220 m. The VIMS Fetch1 AUV completed 100 dives of 3 to 20 min duration over depths of 2 to 70 m.

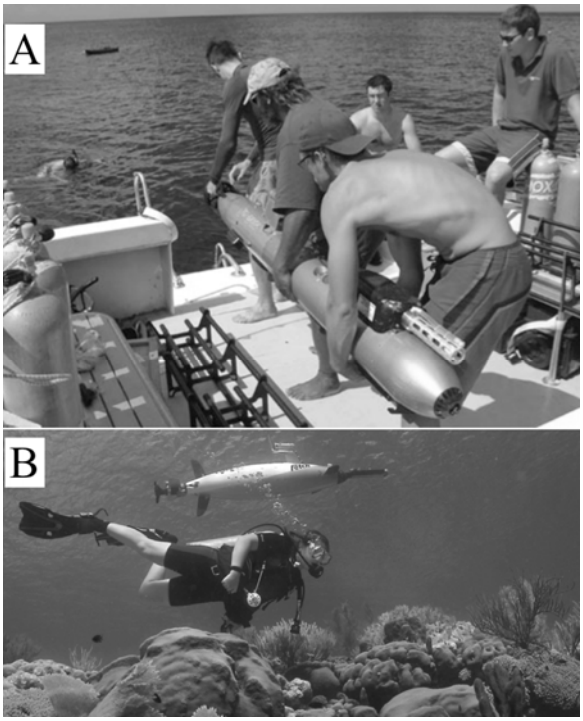

Figure 2: AUV technology used to map Bonaire's reefs. A. Two Gavia-class AUVs were deployed from boats and the shore on the leeward side of Bonaire. B. The VIMS Fetch1 AUV above a diver.

Diver video surveys were conducted using Nitrox SCUBA in a shore-perpendicular direction to a depth of 25 m, to allow ground-truthing of shallow-water AUV surveys. One diver towed a surface float containing a GPS (Garmin eTrex) set to logging mode. A second diver swam directly behind the first, and recorded video from an altitude of 2 m using a Canon Powershot SD950 IS digital camera in an underwater housing, on video setting with a resolution of 1024 x 768 pixels, shooting fifteen frames per second with no additional lighting. Trimix dive operations were conducted at a subset of the 17 areas noted in Fig. 1A, and gave us valuable phototransect data at depths as great as 81 m. Phototransects were also conducted at 40, 30, and 20 m. Video imagery was collected at several levels of resolution (Figs. 3 & 4). Video data were analyzed using Coral Point Count with Excel extensions (Kohler and Gill 2006), using 200 random points per video frame (Fig. 3C).

Results

The expedition successfully collected sonar, video, water quality, and still images over a substantial depth range. These data were used to generate percent cover, Shannon index (H'), and community composition, for comparison of deep vs. shallow reefs and sites along the coast. A full analysis comparing our data to van Duyl (1985) will be presented elsewhere. However, preliminary analysis of the diver

video data shows higher diversity (Shannon index H') and coral cover proceeding from south to north (Tukey multiple comparison, $p < 0.005$), and that deep reefs at all three sites are more diverse than their shallow reef counterparts. Percent cover is also higher with depth for these three sites (Table 2).

Landscape-level patterns can be discerned from photomosaics constructed from AUV datasets (Fig. 4). The fore-reef slope image shown was created from data gathered during a terrain-following dive by Fetch1. The resolution is sufficient for identification of coral genera, percent cover, and community type *sensu* van Duyl (1985). Individual camera frames were automatically adjusted for illumination and color balance. The mosaic was created in ptMac (Kerkus) using four to six control points per frame. Coral bleaching and coral mortality, overgrowth of corals by nuisance species like the tunicate *Trididemnum solidum*, and cyanobacterial tufts are detectable in AUV videos from Bonaire.

The deeper reef below 60 m, and the surrounding sand and rubble bottom in even deeper water, are virtually unexplored. The photo imagery gathered from these deeper dives will be the subject of a future publication. The expedition proved that AUVs gathering video provide a new tool for rapid reef assessment down into the twilight zone, where surface irradiance is less than 1% of that at the surface.

High frequency sonar data provided interesting insights into the geomorphology, reef structure, and

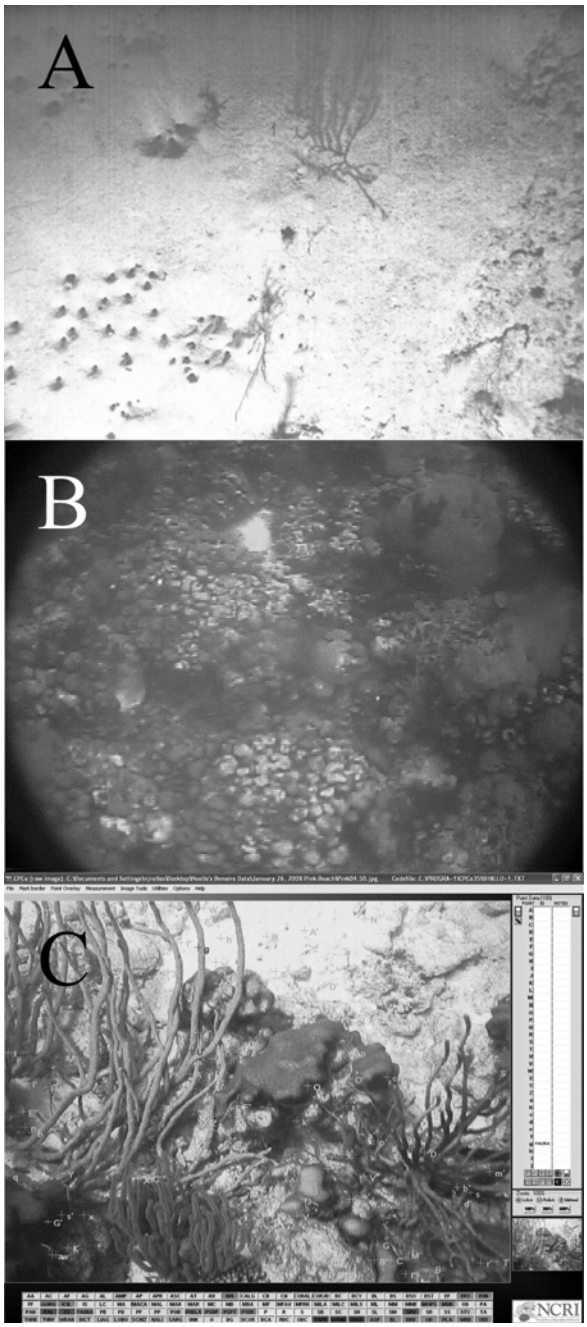

Figure 3: Examples of video imagery collected during the expedition. A. Twilight zone (65 - 200 m) of the reef was imaged by the Gavia AUV. This image is from 147 m. B. Shallow-water landscapes were imaged by the VIMS Fetch1, flying at an altitude of four m. C. Shore perpendicular and parallel transects were conducted by Nitrox and Trimix SCUBA, and were analyzed using Coral Point Count with Excel extensions, shown here in a screenshot (Kohler and Gill 2006).

even habitat utilization by fishes (Fig. 5). Relict reefs, spur and groove formation, double reefs, and bottom type changes can be discerned. Sonar swath widths are much larger than those obtained using video and thus allow the rapid survey and mapping of much larger areas. For example, a 400 m x 400 m area was

completely surveyed at cm level resolution during a single dive by Gavia, using the GeoSwath Plus multibeam module. One of the key features of the GeoSwath Plus is that it collects simultaneous true digital side scan data. The side scan resolution of the 500 kHz system discerns structure down around 3-10 cm depending on survey speed, giving highly detailed images of the seafloor, corals and even fishes in the water column. Using backscatter data, an expert could discern bottom type over the survey area, which was then verified by diver ground-truthing.

Table 2: Mean coral cover and Shannon index (H') at 3 sites surveyed via SCUBA. Sites A, B, C are undeveloped, developed, and marine reserve, respectively. Percent cover (mean) was arc sine transformed for t-test of depth effect, and back-transformed for mean shown above. N is number of video frames.

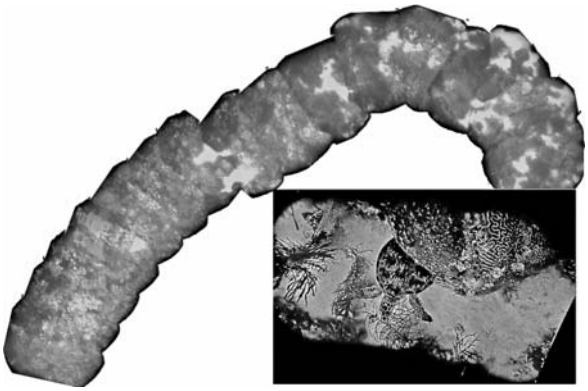

Figure 4: Seascape mosaics can be gathered in a cost-effective manner by AUV technology. VIMS Fetch1 AUV mosaic of fore-reef slope in marine reserve of Bonaire, deeper reef at lower left. Width of frame is 6 m. *Inset:* VIMS Fetch1 AUV image of turtle hiding under brain coral in FL Keys. Flying at lower altitudes allows identification to species level at the cost of reduced swath width (1.5 m), and strong possibility of collision with the bottom.

Discussion

AUV technology can reduce the cost per datum for seafloor mapping, by reducing or even eliminating the need for a ship, which can cost many thousands of dollars per day. AUV surveys also have the potential

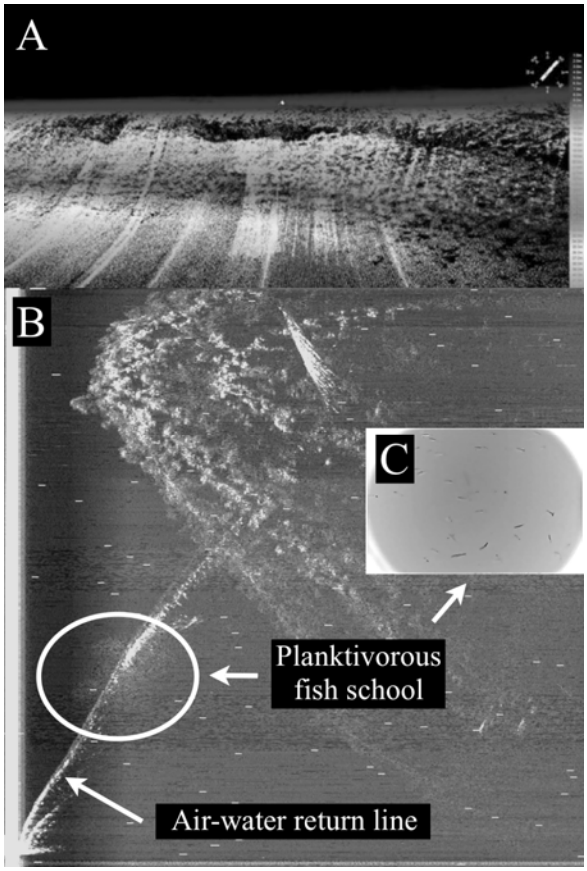

Figure 5: Sonar imagery of Bonaire´s reefs. A. GeoSwath Plus multibeam sonar view of reef, reef slope, and sand channel leading to Klein Bonaire, north of Kralendijk, perspective view facing east, collected by the Hafmynd Gavia AUV. B. MSTL side scan sonar image of fore reef, and water column biota, collected by VIMS Fetch1 AUV. Bright line is sonar return from the air-water interface, and shows AUV turning to begin depth holding. to allow rapid mapping of coral reefs at the landscape level complementing aerial or satellite remote sensing (cf. Andréfouët et al. 2003). When combined with diver ground-truthing, AUV surveys provide a synoptic view of coral reefs at scales from cm to 10s of km, and include depth ranges not easily attained by diving.

The high capital cost of AUV acquisition (US $80,000-600,000) depending on manufacturer and payloads) needs to be weighed relative to the 15 year working lifetime per vehicle currently used by insurers (AC Trembanis, Univ. Del., pers. comm.). AUV reliability for this emerging technology is also a concern with new risk assessment methods for operators under development (Griffiths and Trembanis 2007). Use of AUV mission control software that follows a strict state-machine architecture, used on interplanetary spacecraft where human intervention is not feasible, increases

reliability, and was used on the Fetch1 AUV (Patterson 1998; Patterson and Sias 1999).

The seafloor survey rate of an AUV (32,400 m^2/hr) is about 12x that of the divers, based on swath width (6 m for AUV vs. 1.5 m for diver) and swimming speed (1.5 m/s for AUV vs. 0.5 m/s for diver). The AUVs also gathered two kinds of sonar data and water column data concurrently. Using identical personnel and boat costs, straight line amortizations for one $500,000 AUV (15 years) and $4,000 dive gear (4 years) for two people, the above coverage rate, and assuming the AUV gathers five sets of equally spaced data (two types sonar and water quality, video) vs. video only for the diver, the ratio of cost per datum acquired by AUV compared to a dive team is 0.56. Presently, diver surveys using photo-quadrats and handheld video remain the best choice for detailed survey work where identification to the species level is required. Soon AUVs will be able to terrain-follow at altitudes of 1-2 m required for such work (A Steingrimsson, Hafmynd ehf, pers. comm.).

AUV surveys could pinpoint nuisance species outbreaks so that divers could more efficiently remove them. Diver removal of a tunicate has recently been proposed for Bonaire's reefs (McGrath and Peachey 2008). AUVs could provide quick landscape level resurveys after storm disturbance or coral bleaching events. AUVs are emerging as the tool of choice for bathymetric mapping, assessing fish utilization on reefs, and conducting video surveys of the twilight zone. Their use promises to make the interval between valuable snapshots like that taken by van Duyl (1985) and our survey much shorter in the future. AUV surveys can thus help mitigate against shifting baselines by providing timely, cost-effective data acquisition.

Abstract. The Integrated Coral Observing Network (ICON) program has constructed and installed a series of Coral Reef Early Warning System (CREWS) stations which provide a wealth of high-quality meteorological and oceanographic data in near real-time. CREWS stations date back to 2001 with the deployment of an early buoy-type design in the Bahamas. Beginning in 2002, the program shifted to a pylon-type design which was re-engineered in 2005, resulting in the modern CREWS stations found in the Bahamas, Puerto Rico, the US Virgin Islands and Jamaica. The CREWS instrumentation architecture described herein has evolved over time into a robust package that, combined with a regimen of regular instrument cleaning and recalibration, has yielded a continuous, long-term, high-quality dataset from these harsh marine environments.

Key words: coral, CREWS, monitoring, instruments, temperature, salinity, light, wind, pylon

Introduction

At the National Oceanic and Atmospheric Administration's (NOAA) Atlantic Oceanographic and Meteorological Laboratory (AOML), the Integrated Coral Observing Network (ICON) program has evolved to provide both near real-time marine ecological forecasts ("ecoforecasts" Brandt et al. 2006; CENR 2001) and hourly checks on the status of the sensors it monitors, whether in situ, satellite or other (e.g., Wellen Radar; Shay et al. 2002). Coral Reef Early Warning System (CREWS) stations are a type of in situ station developed by the ICON program at AOML and so-called because of expert system software originally developed by Hendee et al. (1998), and improved by colleagues (Hendee et al. 2007), to monitor data from the SEAKEYS Network in the Florida Keys (Ogden et al. 1994). Newly engineered stations were developed to begin an expansion into U.S. coral reef areas, in response to recommendations by the U.S. Coral Reef Task Force (unpublished memoranda) and United States Executive Order 13089 (Anonymous 1998), and acquired the nickname "CREWS Stations." CREWS stations typically contain all the usual meteorological and oceanographic instruments, as well as instruments of special interest to specific research projects. The CREWS Network is but one in situ network now monitored by the ICON Program.

The present report expands upon Hendee et al. (2006), in outlining the instrumental architecture for CREWS stations.

Materials and Methods

Surface Instrumentation

Surface instruments on the station pylon (Fig. 1) measure light, wind, temperature, barometric pressure, humidity and precipitation. Most measurements are made redundantly by multiple instruments. Instruments which must be isolated from equipment that could block light or wind are mounted away from the station on aluminum masts. Other surface equipment includes five solar panels, a transmitter antenna, a lightning protector and a stand-alone solar-powered navigation light.

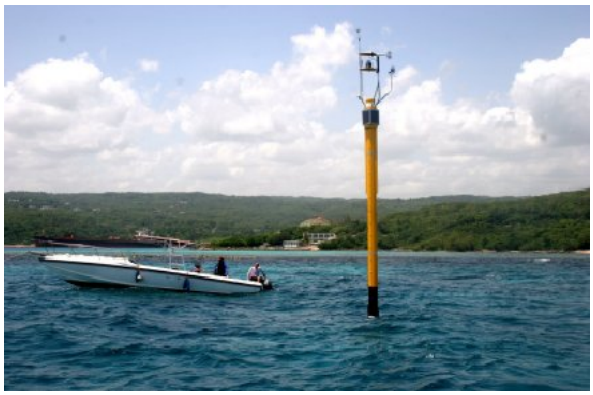

Figure 1. A CREWS Station in Discovery Bay, Jamaica.

Barometer (GE/Druck CS115)

The Barometer outputs a variable frequency which is measured by the data logger's period averaging instruction. It is mounted directly on the station's Control Unit (see below), inside the chamber at the top of the pylon

Wind Monitor, Electronic Compass (RM Young Models 05106, 32500)

The Wind Monitor measures horizontal wind speed and direction. It is connected to the data logger via the Electronic Compass, which accepts pulse counts and direction voltage as inputs and provides voltage outputs (updated once per second) for wind speed and corrected wind direction. Both instruments are mounted on an aluminum mast at 6.5 m above the ocean surface on the west side of the station. The Electronic Compass will be phased out during future maintenance visits to the stations.

Air Temperature Probe (Campbell Scientific Model 107)

The probe uses a thermistor to measure air temperature and is connected to one of the data logger's single-ended voltage channels, and is mounted near the top of the station out of direct sunlight, typically behind one of the station's solar panels.

Weather Transmitter (Vaisala WXT510)

The Vaisala Weather Transmitter (WXT) reports a wealth of meteorological measurements, some redundantly provided by other instruments on the station (air temperature, barometric pressure, wind speed and direction) and some not (humidity and precipitation amount, duration and intensity). Winds are measured acoustically by three ultrasonic transducers. Precipitation is also measured acoustically by a sensor that can distinguish between rain and hail. The WXT has a serial connection to the data logger by which it offers a full report once per minute, unprompted. It is mounted on an aluminum mast at 6.5 m above the ocean surface on the east side of the station.

Surface Light Sensor (Biospherical BIC2104R)

Biospherical Instruments' Multichannel Cosine Irradiance Profiling Spectroradiometers (BICs) are utilized for above water and underwater light measurements. The BICs used on CREWS stations are configured to take four kinds of light readings: three at discrete wavelengths of 305, 330 and 380 nm, and one across the Photosynthetically Active Radiation (PAR) range of wavelengths from 400 to 700 nm. The BICs additionally report low-resolution measurements of temperature and voltage. They communicate with the data logger via serial connections and are prompted for data once every 30 seconds. The surface BIC is mounted on an aluminum mast on the south-facing side of the station for the northern hemisphere.

Underwater Instrumentation

Underwater instruments include those which measure light, salinity, temperature and depth, as well as special deployments of instruments which measure the partial pressure of carbon dioxide and the fluorescent yield of corals. For added flexibility, all underwater instruments use the same type of connector (Impulse BH-4) and cable (multiply-layered with Kevlar, polyurethane, polypropylene and Vectran for maximum strength and resistance to fish bites and bio-fouling). The core instruments (Conductivity / Temperature / Depth sensors and underwater BICs) are doubled up with one set deployed "shallow" and one "deep," or at nominal 1 and 3 m depths. Such placement provides for redundant measurements, for calculating light attenuation, and to detect depth-dependent differences in temperature or salinity.

Conductivity/Temperature/Depth (Falmouth NXIC-CTD)

CTDs report measurements of conductivity, temperature, and pressure, and from these readings they calculate salinity, instrument depth and sound velocity. They also report instrument voltage and are equipped with flash memory and battery backup, and though they draw power from the CREWS station they continue to operate if the station is offline for maintenance. They power themselves up every 6 minutes, run for 30 seconds, and report averaged results from the run via RS-232 connections. They are mounted directly on the pylon at the same heights as the shallow and deep BICs. A simpler CT version of the same instrument is connected during station cleanings to provide ground-truth (i.e., validation) measurements.

Underwater BICs (Biospherical BIC2104U)

This is the same instrument as the Surface BIC (see above) except in a different housing. The underwater BICs are mounted on the sun-facing side of the station on extended arms to avoid light shading by other equipment.

SAMI pCO_2 (Sunburst Sensors)

Several Submersible Autonomous Moored Instruments (SAMIs) have been deployed on CREWS stations. One type of SAMI measures the partial pressure of carbon dioxide (pCO_2) and is important to

ocean acidification research. The SAMI pCO_2, being autonomous, is self-powered and logs its data to flash memory for later retrieval, but it also produces a report once per hour which is communicated to the station via RS-232 connection. This report includes a calculated pCO_2 value as well as sea temperature, blanking constants, and raw numbers for intensities at 434, 620 and 740 nm.

Monitoring PAM Fluorometer (Gademann Instruments)

The Pulse Amplitude Modulation (PAM) Fluorometer is an instrument that has seen several successful short-term deployments, most notably at the Bahamas CREWS station during the bleaching season of 2005 (Manzello et al. 2008). It consists of a central distributor box and multiple PAM heads that are deployed in near proximity to live coral specimens in the immediate area. The PAM, which has an RS-232 connection to the data logger, continuously measures a specimen's at-rest fluorescent response (F_o) and, once per hour, measures the response (F_m) to an intense burst of fluorescent light. The fluorescent yield calculated from F_o and F_m may be thought of as a measure of the specimen's photosynthetic efficiency, and the effects of environmental stressors may show up in these yield values before there are any visible signs of stress or bleaching.

Data Acquisition and Transmittal

Control Unit

The Control Unit is a collection of instruments that manage data acquisition and transmittal; this collection is supported by a fiberglass plate and Vectra for instrument and cable attachments. The Control Unit is thus a package that is installed in a hollow space at the top of the station pylon and is accessed by climbing to the top on removable rungs. Except for the navigation light, all station instruments connect to this unit, including surface and underwater instruments, antennae, batteries, solar panels, grounding wires and lightning protector. These connections are made via weather-proof plugs that are uniquely keyed according to purpose to eliminate the possibility of incorrect connections.

Data Logger (Campbell Scientific CR1000)

The data logger constitutes the "brains" of a CREWS station. It communicates with every instrument on the station via analog or serial RS-232 connections. It auto-calculates data averages, minima, maxima and totals. It is programmed to keep track of how many measurements it has received from each instrument and is capable of re-running complex instrument setup routines if communications fail. It summarizes its data once per hour for reporting via satellite (see Transmitter, below). All data are redundantly stored locally in its Compact Flash Module for later retrieval.

Transmitter (Campbell Scientific TX312)

The High Data Rate Geostationary Operational Environmental Satellites (GOES) transmitter is the main communications link between a CREWS station and the outside world. Each station has a 20-second window once per hour to send its data at 1200 baud. Data are currently transmitted plain-text but could be compressed to a binary format to make room in the future for more fields. The TX312 is connected to a satellite transmitter antenna and a GPS antenna on the outside, and has a direct connection to the data logger on the inside.

Radio (Campbell Scientific RF401)

Every station has a Spread Spectrum Radio for short-distance communications, used mainly for downloading data and for troubleshooting. The radio link is frequently used from a boat moored at the station, or from land-based locations within 500 m. Its antenna is mounted directly on the control unit.

Serial I/O (Campbell Scientific SDM-SIO4)

Instruments which communicate via serial RS-232 connections plug into a port on one of two 4-port interfaces which in turn connect to the data logger. Future control units may expand to include three such units (12 serial connections, total).

Power Supply and Peripherals

Batteries (Odyssey Drycell PC 1200 AGM)

CREWS stations use rechargeable dry cell Absorbed Glass Mat batteries. They are typically charged to between 12 and 14 V DC, with battery levels rising during the day when the solar panels are in sunlight and falling during the night. However, the station's power design allows it to continue operating without interruption for more than two weeks even without recharging its batteries.

Solar Panels (BP Solar SX 10M)

Each station has five 10 watt solar panels (i.e., 50 watts total) installed in a ring about the top of the pylon. This arrangement is partly to take advantage of sunlight from different directions throughout the day, but also to keep the panels as close to the pylon as possible to minimize the risk from the high winds of a tropical storm or hurricane. A Double Pole, Double Throw switch is installed between the batteries and solar panels to completely disconnect all power components prior to removing the Control Unit for maintenance.

Navigation Light (Carmanah Technologies Marine 601)

The station's navigation light is an important safety feature, as it not only provides warning of the station's presence but allows it to be used as a navigational aid that is tracked on marine maps and charts. It is completely stand-alone with its own battery supply and solar panels, and operates independently of station operations or downtimes. Each light is programmed with a flashing pattern that is identified on navigational charts.

Lightning Protection (Forestar Lightning Master Static Dissipater 151100; Wonder Bar Grounding Plate, Mark I)

All metallic and electronic parts of the station are connected by copper grounding wires which run down the inside of the pylon, then exit and terminate on a 15.2cm x 5.1cm x 12.7cm porous bronze grounding plate which is mounted underwater near the ocean floor. This keeps all equipment at the same electric potential and eliminates risk of shock to anyone touching more than one piece of equipment at the same time. Additionally, a lightning protector is integrated into this grounding system and is mounted at the highest point of the station above all other instrumentation. The lightning protector makes use of the point discharge principle to dissipate static charges before they can accumulate to the point where lightning streamers (a prelude to a lightning strike) can form.

Timing

Timing of events on the station is controlled by a main "scan block" of instructions repeated every five seconds. There is also a block of instructions executed exclusively at data logger startup. Table 1 depicts the series of events for data acquisition and transmittal.

Results

There are many challenges faced when deploying electronic equipment in ocean environments. Station operations may be impacted by marine life, equipment failure and tropical storm activity, among other challenges. Perhaps most crucial is the station's satellite communications system, since in the absence of regular data reports it is impossible to monitor instrument performance and environmental conditions.

The early years of the CREWS program (through 2003) saw several impacts from tropical storms and satellite transmitter failures. As a result, station "uptimes," defined as the percentage of time that stations are operational, held steady near 70%. With modern-era (2005 and since) CREWS stations, uptimes have held steady at 95% and above. In addition, in 2004 the design evolved to include an on-site memory storage module, so even in cases where transmissions have been lost due to weather or equipment problems, data are recoverable during the next maintenance visit. Taking into account this after-the-fact recovery of missing transmissions, station uptimes have fallen no lower than 98.9% since this modern instrument architecture was implemented in 2005.

Table 1: Timing of data acquisition and transmittal.

Timing	Events
startup	The logger program signature is recalculated. The logger clock is reset from GPS time. The transmitter is programmed with its GOES platform ID. Station instruments are initialized and/or programmed.
5 seconds	The logger program executes once. Meteorological instruments (air temperature, barometric pressure, wind speed/direction) are sampled.
30 seconds	Logger diagnostics are sampled. Light sensors are sampled (above and below the surface).
1 minute	The Vaisala Weather Station produces a full report. One-minute meteorological maxima, averages are calculated.
6 minutes	The CTDs produce their reports. The ground-truth CT, if connected, is sampled. The Monitoring PAM Fluorometer samples the at-rest fluorescent response (F_o). Transmitter diagnostics are sampled.
10 minutes	Ten-minute meteorological maxima, averages are calculated.
1 hour	The Monitoring PAM Fluorometer emits fluorescent flashes and measures the responses (F_m). The SAMI pCO_2 sensor produces a report. Hourly averages, maxima, minima are calculated. Error buffers, measurement counts are cleared. The station sends its hourly report via GOES (satellites).
1 day	The logger program signature is recalculated. The logger clock is reset from GPS time.

A graph of transmission uptimes is shown in Fig. 2. CREWS stations are identified by name in Table 2, which also shows "transmission uptimes" vs. "station uptimes." Transmission uptimes count the number of hourly satellite transmissions successfully received as a percentage of the total number of hours in the period,

whereas station uptimes describe the same dataset following the recovery of missing transmissions from the local memory module during a maintenance visit.

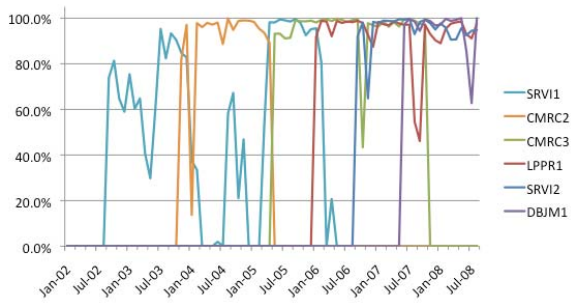

Figure 2. CREWS Station Uptimes, 2002 – present.

The graph shows the evolution of CREWS station performance. Earlier stations (CMRC2 and SRVI1) were of an intermediate pylon design and were prone to more frequent downtimes. The four stations installed since 2005 have much stronger uptimes and most of their outages can be traced to station upgrades or weather events. For example, the affect of Hurricane Dean on LPPR1 uptimes in August of 2007 is clearly seen. Note that one station (CMRC3) was placed on hiatus in October of 2007; its reinstallation is planned for late 2008.

Table 2: Transmission vs. Station Uptimes for CREWS stations, 2002 – present.

Station Name	Location	Station Lifetime	Transmit Uptime (%)	Station Uptime (%)
SRVI1	Salt River, St. Croix, USVI	2002/09 – 2006/06	55.5	80.7
CMRC2	Lee Stocking Island, Bahamas	2003/11 – 2005/04	91.4	93.8
CMRC3	Lee Stocking Island, Bahamas	2005/05 – 2007/10	95.7	99.4
LPPR1	La Parguera, Puerto Rico	2006/01 – present	93.0	99.4
SRVI2	Salt River, St. Croix, USVI	2006/09 – present	95.2	99.5
DBJM1	Discovery Bay, Jamaica	2007/06 – present	95.1	98.9

Discussion

As any marine scientist knows, the ocean is a harsh home for anything that does not live there, and this is why marine instrumentation is expensive and difficult to maintain over long periods of time. The ICON program has now been installing and maintaining stations that measure more than sea temperature for over eight years, and the experience gleaned over this time can serve to save valuable time and resources for other agencies and organizations wanting to conduct similar endeavors. The high quality data we have been able to collect has been used for important research findings (e.g., Hendee et al. 2002; Manzello et al. 2006, 2008) which would have been difficult to obtain without the architecture reported here.

Acknowledgments

NOAA's Coral Reef Conservation Program, and the High Performance Computing and Communications office are gratefully acknowledged for support of the ICON Project and related research. CoralWatch – a flexible coral bleaching monitoring tool for you and your group

U.E. Siebeck, D. Logan, N.J. Marshall

Sensory Neurobiology Group, School of Biomedical Sciences, University of Queensland, Brisbane, Australia

Abstract. The CoralWatch Coral Health Chart, a standardised colour reference card, is an inexpensive, flexible tool that anyone can use for rapid, wide-area assessment of changing coral condition. The charts are used in a growing number of scientific studies as well as by a large number of non-expert visitors to reefs world-wide. Here we describe and analyse two general ways in which the methodology can be used to provide useful data on coral reef condition over time, 'fingerprinting' and long term monitoring of selected colonies. Data stemming from trained and untrained observers, collected via the CoralWatch online database is analysed and compared to data collected by trained observers. Detection of bleaching events and evaluation of recovery rates of corals against temporal and geographic variation in coral colour requires more data collected regularly and frequently by anyone using this globally applicable method.

Key words: colour, coral bleaching, recovery, reef fingerprint, volunteer

Introduction

The CoralWatch Coral Health Chart, a standardised colour reference card, is an inexpensive, flexible tool that anyone can use for rapid, wide-area assessment of changing coral condition (Siebeck et al. 2006). Long-term trends in bleaching and recovery are not well understood at present due to the limited data available. What has been lacking is an objective method that can be used over large spatial scales by volunteers with limited or no training. Various other observer-based methods exist, however, they often require rigorous training and are thus restricted to a relatively small number of scientific volunteers (Miller and Müller 1999).

Measurements with the Coral Health Chart rely on observers finding the closest match between a coral and a colour on the chart. Even with limited training observers are able to do this accurately (Siebeck et al. 2006). Any visitor to a reef can contribute valuable information by simply following the instructions on the card and adding their data to the CoralWatch online database. On the other hand, the chart has been accepted as a useful tool for scientists and is regularly used to assess coral colour or condition (Fabricius 2006; Anthony and Kerswell 2007; Cox 2007; Frisch et al. 2007; McClanahan et al. 2007; Cooper et al. 2008; Spalding 2008).

Here, two general ways of using the charts are discussed, 'reef fingerprinting' and long-term monitoring of individual colonies. We also present a preliminary analysis of the dataset collected through the CoralWatch website.

Material and Methods

Colour measurements

Coral colour was determined as described in Siebeck et al. (2006). Briefly, the Coral Health Chart was held near the selected coral colony. The chart was rotated until the closest match between the overall colour of the colony and a colour on the chart was found. In all cases, the colour score (1-6) of the matching colour was used for the analysis. In previous work a controlled bleaching experiment was used to calibrate the chart with respect to symbiont density and chlorophyll a (Siebeck et al. 2006). It was found that a colour score difference larger than 2 indicates a significant change in symbiont density and chlorophyll a content, and thus bleaching state.

Long-term monitoring of tagged colonies

Twenty randomly selected colonies (10 bleached colonies with colour score < 2, and 10 non-bleached colonies with colour score of > 3 of various species) were marked on the Heron Island Reef flat, Great Barrier Reef, Australia with plastic tags during the 2002 bleaching event. Colour chart measurements were made once every two weeks for 24 months. In each case the observer (Heron Island Research Station Staff) recorded the lightest area excluding the tips.

Fingerprinting

Two independent trained observers collected colour data for 100 randomly selected corals on the Heron Island Reef. Their instructions were to randomly

select a coral in the inner reef flat, measure its colour, then take three steps towards the reef rim, identify the coral closest to them and record the colour of that coral. The observers were instructed to repeat this selection process until 100 corals were measured. For each coral, the observers noted both the lightest and darkest area excluding the tips of branching corals. Data were collected in this way during the 2002 bleaching event (Heron Island, March) and during the winter after the bleaching event (Lizard Island, Green Island and Heron Island, July).

Volunteers using the Coral Health Chart followed the instructions on the chart (as above) and entered their data via the CoralWatch website. Any suspected mistakes in the dataset were removed before analysis. The following information in the dataset was used to detect mistakes: entries labeled with the words "test" or "practise", exact replicates of nearby entries, entries of corals with exactly the same colour score, or entries missing critical data fields, such as 'location', 'date' and 'colour scores'. The data of all volunteers that entered at least 10 datapoints were included. The cut-off was set arbitrarily to ensure that the volunteer had reasonable experience with the method and shown some enthusiasm for it.

Long-term datasets for sites in Australia (Heron Island) and Netherlands Antilles (Barracuda Reef and Mushroom Gardens, St. Eustatius) were examined for changes in coral condition over time. A comparison was also made between coral colour data from a site with reported bleached corals (Christmas Island, April 2005) and data from the same site monitored on different dates. Colour scores from different sites (Heron Island, North Keppel Island, Australia and Richelieu Rock, Thailand March 2005) monitored around the same time as the bleaching occurrence were also examined.

Results

Long-term monitoring of 20 coral colonies

Repeated colour measurements of the 20 marked colonies on the Heron Island Reef flat document the recovery process the corals went through following the 2002 bleaching (Fig. 1a). Pair-wise comparisons show that until May there is a significant difference between the group of corals that appeared healthy (group 1) and the group that was visibly affected by the bleaching (group2) (March & early April $F_{1,18}$ >56 p<0.0001; late April $F_{1,18}$ > 16.0, p = 0.001; 8-May: $F_{1,18}$ = 3.1, p = 0.097). As the corals recover this difference disappears and the colours of both groups are similar – although there is a trend for bleached corals to maintain a lower colour score.

In early September, a second sampling period was initiated as the observers noticed minor bleaching after a severe rainstorm. Results show that both groups of corals suddenly bleached again and further recordings document their recovery from that bleaching event. During the event the colours of both groups are similar. The colour before and after the rainstorm is significantly different for group 1 (ANOVA, $F_{1,6}$ = 21.1, p = 0.004) but not for group 2 (ANOVA, $F_{1,12}$ = 3.3, p = 0.097). During the winter months slight fluctuations of the colours of both groups can be observed.

Examples for the variability in recovery rates and timing are shown in Fig. 1b. Colonies 1-3 start to recover at different times within the first month of sampling, while colony 4 does not recover within this first observation phase. At the beginning of the second observation phase colony 4 and 1 show some recovery (colour change of 2-3 scores) until November followed by colony 3 in early December. Interestingly, colony 2 which showed fast recovery in observation phase 1 does not seem to recover from the rain bleaching. This is an example of how the fate of individual corals can be mapped.

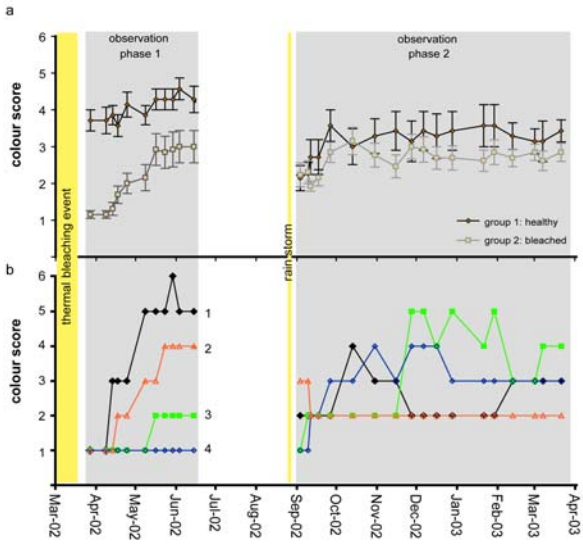

Figure 1: Results for the repeated colour measurements of the 20 corals on the Heron Island Reef Flat following the bleaching event in early 2002 and a second bleaching event caused by a rainstorm at a low tide. a) The average colour scores (mean ± se) are given for healthy corals (group1) and bleached corals (group2). b) Colour change of 4 example colonies showing variability of responses during the observation phases following the two bleaching events.

'Fingerprinting' the reef

Trained observers

The distribution of coral colour on the Heron Island Reef flat during the 2002 bleaching is significantly different from the distribution measured in July (ANOVA, $F_{1,237}$ = 339, p < 0.0001; Fig. 2a). In March, the distribution is skewed and most corals have a

colour code of 1, which represents white coloration. In July, the frequency distribution appears more normal and very few corals have a colour code of less than 3.

A comparison of the colour of 438 corals around the Heron, Green and Lizard Island Reefs in July 2002 shows that the colours on the three reefs have a similar distribution (Fig. 2b). There is no significant difference between the colour scores of corals from Lizard Island and Green Island during July 2002 (ANOVA, $F_{1,259} = 0.098$, $p = 0.8$) while the colours of the Heron Island Reef in the same month are significantly darker than those of the other two reefs (ANOVA, $F_{2,435} = 5.4$, $p = 0.005$).

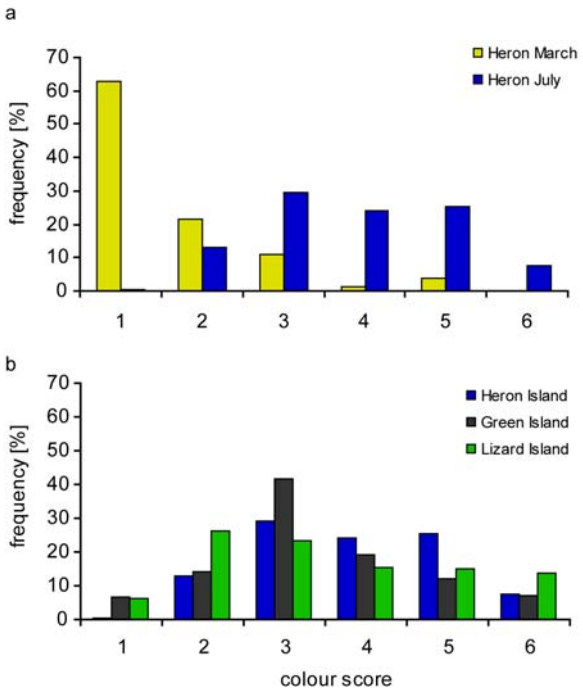

Figure 2: Results of the 'fingerprinting' survey. Distribution of coral colour a) on the Heron Island Reef flat during (March) and after (July) the 2002 bleaching event and b) for a total of 438 corals on the Heron, Green and Lizard Island Reefs in July 2002.

Untrained observers (online database)

Data from 246 sites in 44 countries have been collected and reported by 440 different volunteers (CoralWatch 2008). A bleaching event was reported anecdotally in April 2005 at Christmas Island. Average colour scores were found to be measurably lower (~2 scores) than those observed in October 2005 and October 2006 at the same site (Fig. 3a). Scores were also lower than those from Heron and North Keppel Islands (Australia) and Richelieu Rock (Thailand) measured one month before (Fig. 3b).

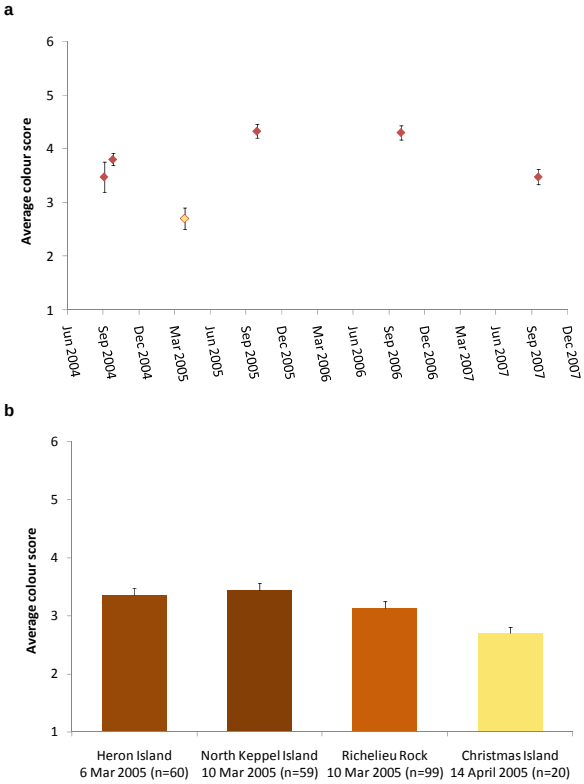

Figure 3: Results of volunteer 'fingerprinting' surveys. Average daily coral colour scores for a) all days that monitoring occurred at Christmas Island sites and b) Heron Island, North Keppel Island (Australia) and Richelieu Rock (Thailand) in March 2005 and Christmas Island in April 2005. Note: Brightness of colours shown using a brown hue in these two graphs provide a rough approximation of the actual average coral colour scores measured.

The largest datasets stem from 3 reef sites, Heron Island (Australia) as well as Barracuda Reef and Mushroom Gardens at St Eustacias, (Netherlands Antilles). Corals at Heron Island Reef observed between 2003 and 2008 show a slight trend of lighter coral colours in spring (Sep to Nov) and darker colours in autumn (March to May) (Fig. 4a). Irregular monitoring occurred in some years, with frequency of data collection varying throughout the year. Data that has been collected more frequently and regularly at both Heron Island (May to Oct 2003) and the Netherlands Antilles show less fluctuation in coral colour over time (Fig. 4b and 4c).

Some slight variation between sites is seen in regard to overall average colour scores, with the coral colour at Heron Island Reef being darker than both Barracuda Reef and Mushroom Gardens (Fig. 4d).

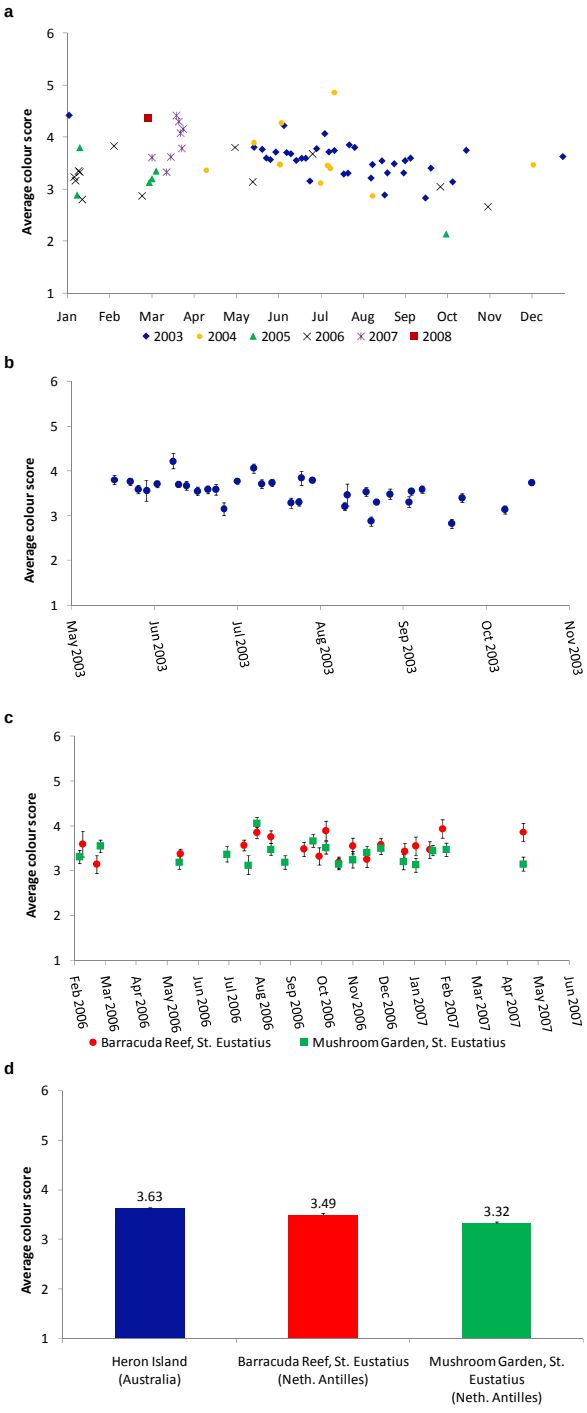

Figure 4: Long term data sets of volunteer 'fingerprinting' surveys. Average daily colour scores (mean ± se) are shown for a) all days that monitoring occurred at Heron Island, displayed over an entire year from 2003 to 2008, b) Heron Island from May to October 2003 and c) Barracuda Reef and Mushroom Gardens (St. Eustatius, Netherlands Antilles) from February 2006 to April 2007. d) Overall average colour scores for long term data at Heron Island, and St. Eustatius.

Discussion

The CoralWatch Coral Health Chart provides a six point scale with which changes in coral colouration, as an indicator of symbiont density, can be measured. This scale can be incorporated in any existing monitoring methodology. Here, an example of two methods proposed to be useful for the wider community are presented: 'fingerprinting' of randomly selected corals and long-term monitoring of specific colonies. The former method leads to large-scale information about the general condition of a reef while the latter method can be used to detect condition changes of individual colonies. At present, the fingerprinting method is better suited to untrained volunteers, such as tourists as even a single visit to the reef can yield useful data when added to the general database. In the future, marked coral colonies, along permanent transects, will provide the opportunity for anyone to participate in long-term monitoring of specific coral colonies. Benefits gained by involving non-scientists are not only due to large amounts of data gathered but also include education and an increase in general awareness of environmental problems, such as global warming and its consequences (Pfeffer and Wagenet 2007).

Repeated measurements of 20 colonies on the Heron Island Reef flat allow the documentation of the condition change of a group of corals, some of which were affected by the 2002 bleaching event. Within six weeks of the first measurement, most bleached corals had recovered and their colours were similar to those of the healthy corals. Two corals had not recovered at that time, which is why the average colour score of the bleached groups is lower than that of the healthy group. It is interesting to note that even the corals that appeared healthy during the bleaching event show a slight darkening in the months following the bleaching, and it is possible that they were also affected by the bleaching event. On the other hand, the possibility exists that the darkening is due to annual changes in symbiont density (Fitt et al. 2000).

The data for individual corals indicate that different recovery timeframes exist. Indeed, there is evidence that coral species have different temperature and time thresholds at which they bleach (Berkelmans and Oliver 1999; Marshall and Baird 2000; Berkelmans 2002) and that this may be true for recovery as well (Hueerkamp et al. 2001). However, more data are needed to detect species-specific patterns.

The first survey period ended in winter, when it appeared that the coloration of the corals would remain relatively constant. However, the same observers noticed that the reef appeared bleached after a severe rainstorm and initiated the second survey period. Both original coral groups were affected, and it appeared that the corals belonging to the group classified healthy during the March

bleaching was actually affected more than the previously bleached group. On average, recovery of both groups was faster after the rain bleaching compared to the bleaching in March, presumably because the salinity returned to normal within just a few hours. This is a good example of how non-expert observers can use the charts to quantify changes in coral health.

Unlike the long-term monitoring of specific coral colonies the 'fingerprinting' protocol is not dependent on the presence of permanent transects and is thus suitable for any interested visitor on any reef worldwide. The 'fingerprinting' method is able to pick up differences between as well as within bleached and recovered reefs. It appears that corals on southern reefs (Heron Island) are relatively darker than corals on northern reefs (Green Island and Lizard Island), and that corals on the Heron Reef flat had made a significant step towards recovery by July.

Untrained volunteer observers collecting CoralWatch data provide a measure of coral condition over time, increasing the chance that a bleaching event will be detected while supplying baseline data that highlights temporal or geographic variation in coral colour. Bleaching events, such as those at Heron Island and Christmas Island, are evident as lower average colour scores when compared against this baseline data.

These data are publicly available and can be reported and used by anyone to make general comparisons of coral condition. Correlations can be made with recorded time of day, weather conditions, coral types, sampling activity and water temperature (CoralWatch 2008), as well as with information from other complimentary datasets on reef condition, such as Reefbase, Coral Reef Watch or Reef Check.

A measure of long-term fluctuation in coral condition is provided in better resolution by following individual colonies over time and could include volunteers observing permanent transects at select sites. Schools and tourism operators returning regularly to the same sites are well suited to monitoring long term trends in coral colour change. Hundreds of recreational divers have registered through Project AWARE and are including CoralWatch monitoring in their dive training and regular dive trips. Other uses of the CoralWatch method include impact assessments, as are being performed by OceanWay in Hong Kong to measure the potential effects of dredging on corals.

More data collected on a regular basis are needed to better detect trends and identify variables influencing changes in coral colour relating to coral bleaching and recovery and potential natural cycles (for example, see Fabricius 2006). Involving more people in consistent observations or targeted reef monitoring in response to predicted or detected bleaching events is expected to improve the current sporadic or non-existent nature of volunteer and scientific monitoring at many reefs sites.

Acknowledgement

We would like to thank John Hay and Paul Greenfield for funding the project through the University of Queensland Vice Chancellor's strategic initiative, Heron Island Research Station staff, Collette Bagnato, Kylie Greig and the Sustainable Tourism Cooperative Research Center. Thanks also to the Project AWARE Foundation and the hundreds of volunteer AWARE divers, along with tourists, students and scientists, who have contributed their time and enthusiasm in the field and their data via the CoralWatch website.

Testing the generality of acoustic cue use at settlement in larval coral reef fish

A. Heenan [1], S.D. Simpson [1,2], V.A. Braithwaite [1,3]

1) Institute of Evolutionary Biology, School of Biological Sciences, University of Edinburgh, Kings Buildings, Edinburgh EH9 3JT, UK

Abstract. Some settlement-stage larval fish appear to be attracted to reef sound and may, therefore, use acoustic cues when orientating towards their settlement site. However, all work on the *in situ* response of coral reef fish larvae to sound in acoustic playback experiments has been carried out in the same location (Lizard Island, the Great Barrier Reef), and in some cases, using the same reef recording. It is therefore not clear how widespread acoustic cue use is. To test whether sound is a general and reliable indicator of reef settlement site, we conducted a similar experiment in a different coral reef region, where the coral reef habitat and therefore soundscape is less uniform in quality (Bohol, Philippines). Contrary to our predictions, in some cases we found that fish were not attracted to the broadcast reef sound. We suggest that this may be due to an artefact of the reef recording, possibly the location or the time of day the recording was made. Our results indicate that larval fish are more selective in their response to coral reef sound rather than just being innately attracted to generic reef sound. This highlights the need to assess anthropogenic impacts on the natural soundscape, as this could affect the ability of larval coral reef fish to acoustically detect a suitable settlement site.

Key words: coral reef fish, cue, sound, light traps, settlement

Introduction

Ten years ago, it was hypothesised that larval reef fish could use sound to locate a settlement site (Stobutski and Bellwood 1998). There are now data that show that as early as the embryonic stage, coral reef fish can detect sound and their sensitivity to sound increases with age (Egner and Mann 2005; Kenyon 1996; Simpson et al. 2005a). At the time of settlement, damselfish (*Pomacentrus nagasakiensis*) are as equally sensitive to sound frequencies as juvenile-stage fish, and therefore are physiologically able to receive acoustic information (Wright et al. 2005). Additionally, Pomacentridae larvae can determine the direction of a sound source and will swim towards reef recordings broadcast in a choice chamber (Leis and Lockett 2005; Tolimieri et al. 2004). This is not just a general phonotactic response but appears to be specific to reef sound as fish were attracted towards reef recordings, but not artificial pure tones (Leis et al. 2002).

Acoustic playback experiments have shown that reef fish are attracted to light traps broadcasting reef sound over the ambient soundscape (Leis and Carson-Ewart 2003; Simpson et al. 2004; Tolimieri et al. 2000), and higher natural settlement rates are seen on patch reefs that were associated with underwater speakers playing reef recordings, in comparison to silent control patches (Simpson et al. 2005b). Generally, settlement-stage fish are more attracted to the higher frequency components of reef sound (made predominantly by invertebrates), relative to the original recording and the filtered lower frequencies alone, so sound appears to be more than just a broad indicator of reef location and may provide specific information used in settlement site selection (Simpson et al. 2008).

The use of sound for orientation during settlement varies among families, however, with some families appearing not to respond to sound cues (Leis and Carson-Ewart 2003; Simpson et al. 2004). What is not yet understood is how widespread acoustic cue use is. With the exception of one study carried out on sub-tropical rocky reef fish (Tolimieri et al. 2000), the remaining seven *in situ* studies that have shown positive phonotactic responses of larval fish to coral reef sound were all carried out at Lizard Island. Four of these studies shared the same single reef recording as the test sound (Simpson et al. 2004; Simpson et al. 2005b; Simpson et al. 2008; Tolimieri et al. 2004), and the remaining three used another (Leis et al. 2002; Leis and Carson-Ewart 2003; Leis and Lockett, 2005). As a result, our knowledge of acoustic cue use

in settlement-stage fish orientation is potentially very location specific and it has not been investigated in any other coral reef area, where the soundscape may be less consistent due to variability in reef quality. We questioned the generality of acoustic cue use by testing the response of larval coral reef fish to sound in a different location. Using the same techniques that have previously been used to assess the attraction of settlement-stage fish to broadcast reef sound at Lizard Island (i.e. coupling light traps with underwater speakers), we carried out a similar experiment on settlement-stage coral reef fish in the Philippines. Light traps collect phototactic larval reef fish at the end of their pelagic phase, and the comparison of catch rates in the sound treated vs. the silent traps can be used to assess the attraction of settlement-stage fish to the broadcast sound treatment (Leis et al. 2003; Simpson et al. 2004; Simpson et al. 2008; Tolimieri et al. 2000). We predicted that if sound is a general and reliable indicator of reef location, it will be used by settlement-stage fish in this different study area, therefore higher numbers of fish would be attracted to the sound, in comparison to the silent control treatment.

Methods

Traps (designed by Ecocean, St Clément de Rivère, France) were set at surface moorings located in a sea channel to the northeast of Pangapasan Island, Bohol, central Philippines (10°01.1'N, 123°56.2'E). The moorings were anchored on a sandy substrate in water of 10-12 m depth. There was no reef present within 50 m of each mooring and they were separated by c. 400 m to prevent acoustic overlap of the different traps broadcasting sound. The area at which the broadcast sound was detectable over the ambient reef sound was estimated to be 20-50 m (see Fig. 1).

Each night, two sound and two silent traps were each pseudo-randomly assigned to a mooring, so each treatment was tested multiple times at each position during the experiment. The sound systems consisted of an MP3 player, a 12V lead-acid battery, 18W Universal Amplifier Module (Kemo-Electronic GmbH, Lanhen, Germany), and an Electrovoice UW30 underwater speaker (Lubell Labs, Columbus, OH, USA). This played the sound treatment on continuous loop through the night, which was a recording taken at 8.40am on the 16th June 2007, at Black Forest Reef, a marine protected area located to the southwest of Bohol (09°31.228'N, 123°40.991'E). The recording was taken using an Edirol R1 recorder, and a HTI-96-MIN omni-directional hydrophone with a built in preamplifier (High Tech, Inc., Gulfport, MS, USA) and processed using Audacity 1.2.6. (a free digital audio editor available at http://audacity.sourceforge.net/) to delete artificial artefacts (e.g. the sound of distant boat engines) and produce a clean one-minute recording.

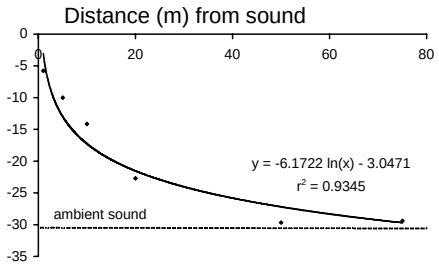

Figure 1. The distance over which the sound treatments were detectable over the ambient sound level. Sound intensity (root mean squared measured in relative dB) was measured at increasing distances from the sound system playing back a pure tone sound.

The experiment was conducted over 21 nights from the 4th-24th July. Traps were deployed at dusk, left overnight and collected at dawn, when the catches were transferred to separate polystyrene cool boxes and transported by boat to a nearby aquarium facility in Matabao, Bohol. Reef fish were separated from the rest of the catch (which consisted primarily of invertebrates and clupeids) and identified to family, or when possible, species level and counted. The fish were then given to Ecocean for rearing for a release scheme.

Analysis

There are no data available on the behaviour of larval fish upon entering light traps, therefore we do not know if it is a fair assumption to treat each captured fish as a statistically independent data point. For this reason, two approaches were taken for the analysis. A sign test, which makes no assumptions on the independence of fish caught, was used to test the null hypothesis that the number of nights with the largest catch would be the same for the silent and sound treated traps. As this test has a low power to detect a treatment difference when the number of testable nights per family is low (after excluding ties), the second approach estimated the effect of the sound treatment on the number of larval fish caught by fitting a generalised linear mixed effects model (GLMM). This method does assume larvae entered the trap independently, however it has the benefit of including the temporal and spatial variation that is characteristic of larval fish distribution and occurrence in light traps. Counts were grouped by family and families for which fewer than 10 individuals were captured over the experiment were excluded. Counts of fish per family were not normally distributed (Shapiro-Wilk test, $W = 0.1878$, $p < 0.001$). A logarithmic link function and Poisson

error distribution was specified as the data set was bounded by zero and the variance in counts per family was not equal. As there was inter-family variation in abundance, the number of fish caught per mooring and the number of fish caught per day over the lunar cycle, these were fitted as random effects. An interaction between sound treatment and family was fitted as a main fixed effect. As a significant trap unit effect was not found it was dropped from the model. The models were fitted using maximum likelihood.

Deviance statistics (estimates of how well the model captures the data) were generated for each model with and without the explanatory variables. To obtain the significance levels of the explanatory variables, the deviance statistics were compared using Chi-square tests. All analyses were implemented in R (R Development Core Team 2007).

Results

Twenty nights of data were collected, with 78 trap deployments (39 sound and 39 silent) as bad weather (on the 8th night) caused all traps to be retrieved early. A sound system failed on one occasion and on another a mooring was stolen, preventing a silent trap from being set, leading to a total of 18 nights data with sound treated and silent control trap deployments.

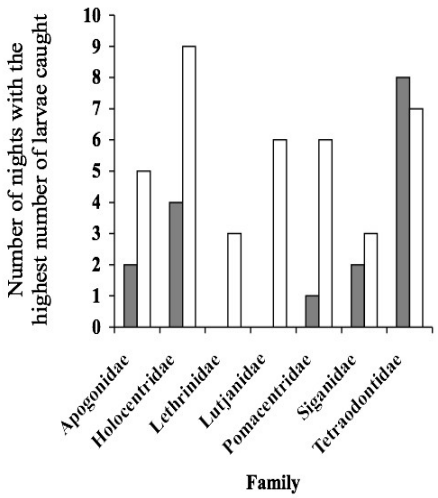

Figure 2. Number of nights with the greatest catch per treatment deployed with speakers (grey) and without (white) from the 4th-24th July 2007, Bohol, the Philippines.

A total of 326 larval coral reef fish from 14 families were caught (see Table 1). The four most common families (Apogonidae, Holocentridae, Siganidae and Tetraodontidae) comprised 75% of the total catch.

Table 1. Summary of catches of settlement-stage coral reef fish larvae caught in light traps with broadcast reef noise (sound) and without (silent). Low catch rates prevented analysis of some of the families. Results (significance levels) of the sign tests (per family) and the generalised linear mixed effects model (GLMM) (families grouped according to their direction of response to the sound treatment) are shown (see methods for details).

Family	Silent	Sound	Total	Sign test	GLMM
Apogonidae	31	12	43	0.226	
Holocentridae	22	13	35	0.133	
Lethrinidae	8	2	10	0.125	< 0.001
Lutjanidae	14	4	18	0.015	
Pomacentridae	13	1	14	0.062	
Siganidae	57	26	83	0.500	
Tetraodontidae	45	44	99	0.500	0.718
Blennidae	1	1	2		
Carangidae	2	2	4		
Chaetodontidae	0	1	1		
Mullidae	2	5	7		
Scaridae	0	2	1		
Sphyraenidae	1	4	5		
Syngnathidae	2	2	4		

Sign tests showed that one family (Lutjanidae) was caught in greater numbers on significantly more nights in the silent traps (see Table 1; Fig. 2).

In contrast, the less conservative GLMM that takes into account other spatially and temporally variable factors found that there was a variable response of fish families to the sound treatment (family: sound treatment interaction, χ^2: 14.41, p= 0.025). When the seven most abundant families were grouped according to their direction of response to the sound treatment, six (Apogonidae, Holocentridae, Lethrinidae, Lutjanidae, Pomacentridae and Siganidae) were caught in higher numbers in the silent traps in comparison to the sound (χ^2: 15.240, p<0.001). There was no difference between the sound and silent treatment in catch rates for the Tetraodontidae (*post hoc* Mann-Whitney, W: 118.5, p= 0.718).

Discussion

Settlement-stage larval fish were not attracted to the broadcast reef sound. We predicted that if fish could detect and were attracted to reef noise, there would be higher catch rates in the sound treated light traps. The opposite effect was found for the Lutjanidae, where significantly more fish were caught in the silent than in the sound treated traps. There was an overall

trend, when the abundant families were grouped together, for higher catch rates in the silent treated traps. This result is in contrast to those from four previous acoustic playback studies in which fish (of the families caught in this study: Apogonidae, Holocentridae, Lethrinidae and Pomacentridae) were attracted to broadcast reef sound (Leis and Carson-Ewart 2003; Simpson et al. 2004; Simpson et al. 2005b; Simpson et al. 2008). Our results are consistent with those of Leis et al. (2003), who demonstrated that the attraction of settlement-stage apogonids and pomacentrids to sound varied with location. In that study larvae responded positively to the sound treament at inshore but not offshore sites. There are two possible explanations for the lack of congruence with the findings that settlement-stage fish are attracted to reef sound: 1) there was a negative effect between the design of the traps used and the sound treatment 2) there was an artefact of the recording we broadcast for the sound treatment that acted as a repellant to settlement-stage larval fish.

We used a light trap that has a more open entrance than did those used at Lizard Island. This could mean that fish entering the trap were more vulnerable to predation. So if for example, the sound treatment also attracted predators, this could reduce the number of fish caught. Without any data on the rate of predation on fish entering the trap, this explanation, as with any other on a potential trap type and sound treatment interaction, is speculative. However, this is unlikely to have contributed to our finding that settlement-stage fish were caught in higher numbers in the silent traps, as when the Ecocean traps were used at Lizard Island in 2007-8, the most commonly caught families were more abundant in the sound treated traps (Heenan, pers. obs). This asymmetry also is unlikely to be the result of the fish caught in our study being unable to detect the sound treatment, as if this were the case, one would expect an equal number to be caught in the silent and sound treated traps. Without further experimentation, we do not know if this represents a general avoidance of coral reef fish larvae to sound in this region of the Phillipines or if it was specific to the recording used for the sound treatment.

There are two aspects of the recording itself that may have been repellent to settlement-stage coral reef fish. The first concerns the variation in reef sounds: they vary with time (season, moon phase and time of day); and the biological chorus has cyclical patterns in intensity, peaking during summer evenings around the new moon (Cato 1978; Radford et al. 2008). This coincides with when larval fish arrive in highest density to recruit to the reef (Dufour and Galzin 1993; Irisson and Lecchini 2008). While settlement-stage fish are attracted at night to nocturnal reef recordings (Leis and Carson-Ewart 2003; Leis and Lockett 2005; Simpson et al. 2004; Simpson et al. 2005b; Simpson et al. 2008; Tolimieri et al. 2004), they do not respond to nocturnal reef noise during the day (Leis et al. 2002; Tolimieri et al. 2004). Due to logistical reasons, the test recording we used was taken in the morning (8am), however *in situ* observations of released larvae showed that they orientate away from the reef during the day in Australia (Leis and Carson-Ewart 2002). In this study larval fish were repelled by a daytime recording, therefore this result supports the diel dependent nature of larval attraction to sound, suggesting that 1) they can perceive the difference between the sound of a reef at night and during the day and 2) they use this information to time their approach to the reef.

The second aspect of the test recording relates to the difference between the area where it was taken and played back. Located 60 km away, the recording was chosen as it was a marine protected area, with high fish diversity and abundance, and we believed it to be a biologically rich in sound. Some settlement-stage larval fish appear to imprint to their natal reef site by olfaction (Arvedlund and Nielsen 1996; Arvedlund et al. 1999; Gerlach et al. 2007), and so as embryonic stage fish can hear sounds (Simpson et al. 2005a) it is plausible to suggest that imprinting may also occur to natal reef sounds. If this were the case in this study fish may have been affected by the non local aspect of the test sound. However, in four separate studies, larval fish at Lizard Island were attracted to a recording taken at Feather Reef, which is located over 300 km away, which shows that larval fish will respond to a non local recording. Instead, we suggest that the test recording sounded sufficiently different from the ambient acoustic conditions that were characteristic of the playback site (a channel flanked by two reefs that had degraded to urchin and algal dominated reefs), that it caused fish in this area to avoid the played back sound.

This is the first *in situ* acoustic playback experiment on settlement-stage coral reef fish performed outside of the Great Barrier Reef, and we found that in contrast to these previous studies, catches of larvae decreased due to the sound treatment. This suggests that larvae are more selective in their response to reef sound, rather than having a generic innate attraction. Given the potential for habitat degradation, overfishing and anthropogenic sources of sound to modify the natural soundscape, acoustic surveys are needed to compare the soundprints of different reefs. Furthermore, experiments are required to determine the selectivity of acoustic cue use in settlement-stage fish, as it seems possible that this could affect the

ability of larvae to acoustically detect a suitable settlement site.

Acknowledgements

We thank G. Lecallion and S. Lourie from Ecocean for the opportunity to carry out this study, equipment and funding. We are grateful to A. Amejan, S. Green, W. Mellonieda and M. Priest for logistical support and J. Hadfield for statistical advice. We also thank an anonymous reviewer for comments which improved the manuscript. This work was funded by a Natural Environment Research Council (NERC) postgraduate studentship (grant number NER/S/A/2006/14128) a NERC Postdoctorate Fellowship (grant number NE/B501720/1).

Abstract. The Florida Area Coastal Environment (FACE) research program gathers a variety of data related to water inputs into the coastal zone of southeast Florida. The water inputs studied include treated wastewater discharges, inlet flows, and upwelling events. Measurements include currents, nutrients, microbial contaminants, and stable isotopes. This report provides a glimpse of the data collected in this program. Data collected from the Boynton inlet point to the significance of this discharge as a source of nutrient and microbiological loads to coastal waters and demonstrate the importance of accounting for all major discharges in order to fully understand the impact of land use and water management decisions on coastal resources.

Key words: wastewater, inlets, Florida, nutrients, microbial contaminants.

Introduction

The Florida Area Coastal Environment (FACE) program is an ongoing research effort lead by the NOAA's Atlantic Oceanographic and Meteorological Laboratory in Miami, FL since 2004. The broad objectives of the studies include: (1) quantify the sources of selected nutrients and microbial contaminants, (2) ascertain the relative contributions of those sources to the nutrient budget and microbiologic loads of the region, and (3) determine the likely exposure of certain coral reef resources to those nutrient and microbiologic sources. The study area of FACE covers 364 km of coastline in the counties of Miami-Dade, Broward, Palm Beach, and Brevard, and includes six treated wastewater plants (TWWPs): Miami Central, Miami North, Hollywood, Broward, Boca Raton, and South Central (Fig. 1), which together contribute ~1 million cubic meters (284 millions of gallons) per day to the region. In addition, this coastal area receives fresh water discharged through six inlets, from the Miami Harbor inlet in the south to the Boynton inlet in the north (Fig. 1).

The FACE field campaigns have included inlet and outfall plume tracer studies, nutrient surveys, ocean current measurements via ADCP, microbiological survey studies, and stable isotope studies on a variety of research vessels (NOAA's R/V Cable and R/V Nancy Foster, R/V Coral Reef II, and the University of Miami's R/V Walton Smith). These field programs are outlined in Table I.

Material and Methods

Tracer Studies. An outfall tracer study was conducted on the Hollywood outfall in June 2004 by injecting sulfur hexafluoride (SF_6) gas into the outfall pipe over the course of six days. Methods for this study are available in Wanninkhof et al. (2005). A second outfall tracer study was performed near the outfall of the South Central Regional Waste Water Treatment Plant (SC) in 2007. In the latter study, rhodamine-WT dye (RD) was introduced into the effluent flow for a 48-hour period commencing on 26-Feb-2007. RD was also introduced into an outgoing tidal flow in the Boynton Inlet (26°32'43" N, 80°2'30"W), on 22-Feb-2007 to track the discharge of the inlet. The RD was tracked by ship using a towbody equipped with a hose and a pumping system to obtain water samples. Two sensors (YSI model 6600, for temperature, RD, chlorophyll, salinity, and

depth) were moored at the bottom and at mid-water above a location on Gulfstream Reef.

Inlet Intensive Studies. In addition to the tracer study at the Boynton Inlet, two 48-hour intensive water sampling periods were conducted at that location. The objective was to collect water samples over four complete tidal cycles in order to investigate the nutrient and microbial loads contributed by this inlet. The first sampling event was conducted June 4-6, 2007 and the second on September 26-28, 2007.

Current Measurements. Three in-situ Acoustic Doppler Current Profilers (ADCP, RD Instruments) were installed to measure ambient currents in the area of the SC. A 300-kHz ADCP was installed at the south end of Gulfstream Reef (26°29.272'N, 80°2.35'W, 16.4 m depth, deployed 29-Sep-2006 to 1-Jul-2008). A 600-kHz ADCP was installed at the north end of Gulfstream Reef (26°31.247'N, 80°1.939'W, 14.5m depth, deployed 4-Apr-2006 to 9-Aug-2007).

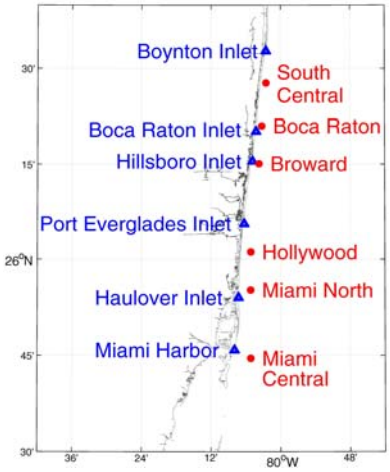

Figure 1. Locations of coastal inlets (triangles) and treated wastewater treatment plant outfalls (circles) in the FACE area of study.

Thirdly, a 1200-kHz ADCP was installed midway between the Boynton Inlet and the north end of Gulfstream Reef (26°32.004'N, 80°2.146'W, 14.8 m depth, deployed 20-Feb-2007 to 13-Apr-2007). These ACDPs yielded ambient current direction and magnitude measurements through the water column from near the ocean bottom to near the ocean surface. They also recorded ambient water temperature and pressure.

Nutrient Measurements. Water samples from bottom, mid, and surface waters at fifteen locations around the SC and the Boynton Inlet (Fig. 2) were obtained on bimonthly cruises for one year (see Table 1) and analyzed for a variety of nutrients, including ammonia (EPA Method 349.0; Zhang et al. 1997a), nitrate + nitrite (EPA Method 353.4; Zhang et al. 1997b), orthophosphate-P (EPA method 365.5; Zhang et al. 2001), total phosphorous (EPA Method 367.0; Zhang et al. 1998), and silicate (EPA Method 366.0; Zhang and Berberian 1997). Analyses were performed on a modified 5-channel Perstop Auto analyzer generally within three hours after sample collection.

Microbial Studies. Water samples collected from all cruises and inlet studies in Table 1 were analyzed for a variety of microbes, including fecal-indicating bacteria (FIB), pathogens, and source tracking markers. Viable enterococci FIB were enumerated using IDEXX Enterolert™ (EPA 2003). *Cryptosporidium* oocysts and *Giardia* cysts (protozoan pathogens) were determined by immunomagnetic separation and immunofluorescent microscopy (EPA 2001). Water samples for molecular analysis of viruses, bacteria, and source

tracking markers (1 L) were processed by membrane filtration prior to nucleic acid extraction. Water samples for analysis of protozoans (>100 L) were processed using FiltaMax™ cartridges (IDEXX). RNA viruses (noroviruses and enteroviruses) were analyzed by real-time quantitative reverse-transcription PCR (qRT-PCR). Standard PCR was used for detection of *Campylobacter jejuni*, *Salmonella* spp., *Escherichia coli* O157:H7, *Staphylococcus aureus*, human-specific enterococci, and adenovirus (LaGier et al. 2004). Real-time PCR (qPCR) was used to quantify enterococci, human-specific *Bacteroides*, and human-specific *Methanobrevibacter smithii*.

Results

Dilution of the outfall plume based on tracers. The tracer study conducted on the Hollywood outfall in 2004 demonstrated the utility of using SF_6 as a tracer for study of the farfield plume (i.e., > 400 m from the outfall). Transportation and dispersion of the plume depended on the physical oceanographic conditions encountered during the time of the study. The plume was incorporated into the ambient ocean current, generally northerly during these experiments, and remained in the upper portion of the water column following the initial rise out of the outfall pipe. The relationship determined for the dilution of treated wastewater (Dilution = 212 x distance [km] from the outfall, Wanninkhof et al. 2005) over 60 km was consistent with earlier outfall studies performed in that area within 2 km (Proni et al. 1994). In the 2007 tracer study, RD results suggested a dilution of approximately 233:1 in the area around the SC boil.

Currents. ADCP data for the 2004 tracer study were collected in the region of Dania Beach, FL. These currents were generally northward with an average flow of about 20 cm/s measured at 1.5 km from shore; although reversals to the south were observed during the six-day period of the study (Wanninkhof et al. 2005). ADCP data were collected near the SC outfall over a longer time frame. As observed in the area of the Hollywood outfall, currents to the south were measured; however, a northern current was measured ~86% of the time. The mean northward current was ~32 cm/s to the north at 3 m depth, tending to decrease with depth below 3 m. In addition, there was a mean eastward component to the current, measured at 6 cm/s at 3 m depth. The eastward component was fairly uniform with depth.

Nutrients. Only a small subset of the nutrient data collected to date is presented here. Averaged (over surface, mid, and deep-water values) nitrate + nitrite ("N+N", Fig. 3) and silicate concentrations (Fig. 4) were elevated in the area of the Boynton Inlet and the Lake Worth lagoon (Fig. 2) relative to surrounding areas, including in comparison to concentrations measured on and around the boil of the SC treated wastewater outfall. Ammonia concentrations (Fig. 5) were sometimes elevated in the lagoon (Oct 2007, July 2008) and sometimes at the boil (Aug 2007, May 2008). The highest average concentrations of orthophosphate-P were measured in the lagoon and inlet (0.54 and 0.2 µM, respectively; n=6 bimonthly cruises). Concentrations were lower at the boil (0.07 µM) and elsewhere (<0.04 µM).

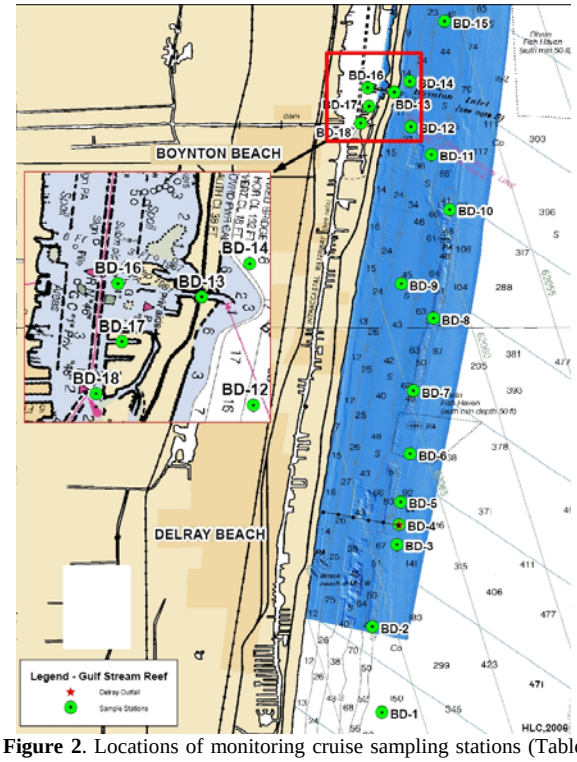

Figure 2. Locations of monitoring cruise sampling stations (Table 1). The SC ocean outfall is at BD-4, the Boynton Inlet at BD-13. Samples from within the Lake Worth lagoon are BD16, 17, and 18.

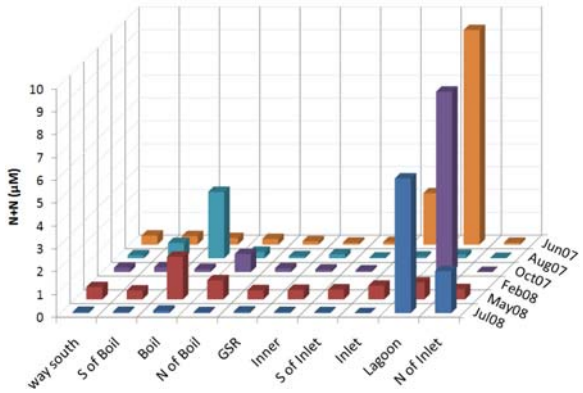

Figure 3. Concentrations of nitrate+nitrite from bi-monthly cruises. Referring to Figure 2, averaged concentrations are given for Way South = BD1 and BD2; S of Boil = BD3; Boil = BD4; N of Boil = BD5; GSR = BD6, BD7, BD8, and BD10; Inner = BD9; S of Inlet = BD11 and BD12; Inlet = BD13; Lagoon = BD16, BD17, and BD18; N of Inlet = BD14 and BD15.

Two 48-hour sampling intensives at the Boynton Inlet examined the nutrient loads from a total of eight ebb tides. A side-looking ADCP provided accurate flow data. A comparison was then made between the nutrient loads from the SC outfall (Koopman et al. 2006) and that from the nearby Boynton Inlet, shown in Table 2. Although there was significant variance in the Inlet ebb tide pulse masses, the average daily loading significantly exceeded or was comparable to that from the SC outfall.

Table 2. Mass loadings (kg/d) on ebb tide pulses from the June and September Boynton Inlet experiments (left) compared to the output of the South Central TWWP (right). For phosphorous, intensive units are dissolved inorganic phosphate; for SC the units are total phosphate (*), which includes particulate phosphate.

	June Intensive				Sept Intensive				Inlet Ave	SC Ave
	1	2	3	4	1	2	3	4	Mass	Mass
N+N kg [N]	204	99	138	23	569	476	303	105	479	191
Si kg [Si]	1196	955	1452	798	5255	4134	2248	1215	4313	
P kg [P]					362	195	116	31	352	79*
NH_4 kg [N]	171	68	89	41	599	524	286	78	464	545

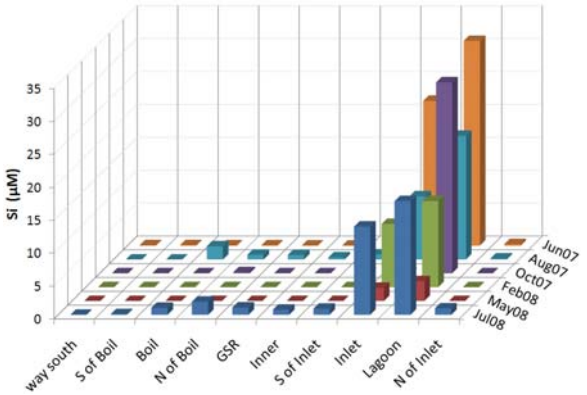

Figure 4. Concentrations of silicate from bi-monthly cruises. Sample denotations are as described in Figure 3.

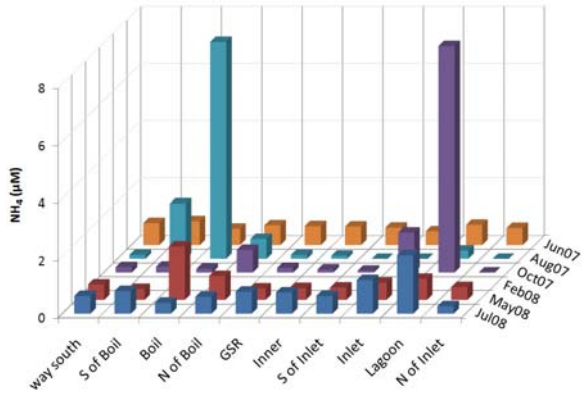

Figure 5. Concentrations of ammonia from bi-monthly cruises. Sample denotations are as Figure 3. No measurements were obtained from the February 2008 samples.

Microbiology. Only a small subset of the data collected to date is presented here. The inlet appeared to be a source of microbial contaminants to near shore waters as indicated by a higher percentage of positive detections for pathogens, FIB, and source tracking markers associated with the outgoing tide versus the ingoing tide (Fig. 6). A variety of microbial contaminants were detected in outgoing tides from the inlet. In comparison, water samples taken from the boil and near the bottom of the SC outfall (the closest outfall (the closest outfall to the Boynton inlet) did not yield positive results in February 2007 (Table 1). A low amount of enterococci DNA (<30 genome equivalents) was detected at the SC boil during a July 2008 cruise, and the abundance declined with distance from the outfall (Fig. 7).

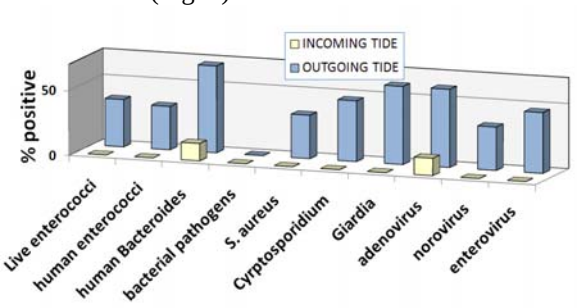

Figure 6. Detection of microbial contaminants for incoming vs. outgoing tides during a 48-hr intensive study at the Boynton inlet. Data show the percentage of samples showing positive detection for microbial contaminants out of 15 discrete time points. "Bacterial pathogens" is a composite for *Campylobacter jejuni*, *Salmonella* spp., and *Escherichia coli* O157:H7.

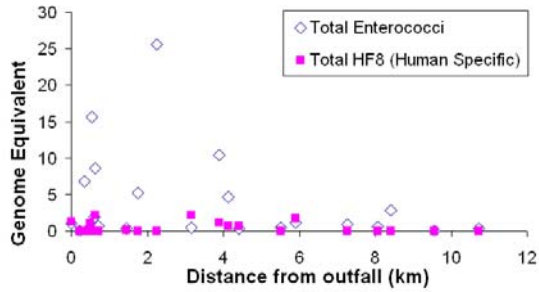

Figure 7. The abundance (genome equivalents) of enterococci and a human-specific *Bacteroides* (HF8) as measured by qPCR versus distance from the SC outfall (data from July 2008 R/V Walton Smith cruise).

Table 3. Microbiological data from surface water and bottom (btm) of the SC wastewater boils from a Feb. 2007 cruise aboard the Coral Reef II. No detection is indicated by "nd".

Target	surface	bottom
Live enterococci	-	-
human *Bacteriodes*	-	-
human enterococci	-	-
adenovirus	-	-
norovirus	-	-
MS2 phage	-	-
enterovirus	-	-
Salmonella ssp.	-	-
S. aureus	-	-
Cryptosporidium/100 L	2	nd
Giardia/100 L	3.4	nd

Compared to the SC outfall, samples from other outfalls yielded higher abundances of *Cryptosporidium* oocysts and *Giardia* cysts (Table 4) In general, the abundance of protozoan cysts appeared to dilute with distance because cysts were not detected at a distance of 1 km from the outfall (data not shown).

The abundance of norovirus and the human-associated FIB, *M. smithii* also were higher at the other outfalls tested (Table 4). These data provide a measure of total abundance; the percentage of viable organisms currently is unknown and is potentially low for these chlorinated effluents discharged into sun-lit coastal waters.

Table 4. Abundance of *Cryptosporidium*, *Giardia*, human-specific FIB, *M. smithii*, and human viral pathogens of the norovirus group measured by qPCR from surface water of wastewater boils from a Feb. 2008 cruise aboard the R/V Nancy Foster. (GE = Genome Equivalents).

Discussion

The data derived from the FACE work to date indicate that: (1) for the majority of the time the ambient current at the SC outfall vicinity flows to the north (slightly northeast) approximately 86% of the time; (2) minimal downward mixing of the effluent plume at any outfall was observed within the limits of the observations; (3) The water quality measurements made in the vicinity of the SC outfall showed that there was not a significant elevation of nutrient concentrations (N+N, NH_4, P) in samples at the GSR compared to the southernmost samples (in northward current regimes); (4) The flux of nutrients from the Boynton Inlet significantly exceeds (N+N and P) or is on the same order (NH_4) as that of the nearby SC outfall, indicating the importance of inlets as a source of nutrients to the coastal ocean.

In the case of microbial contaminants, the levels of microbial contaminants observed in the immediate vicinity of the southern outfalls and in some outgoing tides of the Boynton Inlet would be of public health concern were they in drinking water or full-body-contact recreational water. However, given the rapid dilution observed, it is likely that infectious risk to humans and fisheries is very low, except potentially in the immediate vicinity of the southern outfall boils.

The FACE project has collected a variety of data, including nutrient, microbiological, and oceanographic information to help understand the processes that effect Florida's coral reef habitat. The data presented here highlight the need to assess the coastal zone in a cohesive way, especially if data will be used to determine the impacts of land-based pollutants, and for the formulation of science-based regulation.

Acknowledgement

Acknowledgement is given to Source Molecular for analysis of *Cryptosporidium* oocysts and *Giardia* cysts. We thank the NOAA Hollings Marine Laboratory, Charleston SC for analysis of *M. smithii* and RNA viruses for selected samples. This research was carried out in part under the auspices of the Cooperative Institute for Marine and Atmospheric Studies (CIMAS), a joint institute of the University of Miami and the National Oceanic and Atmospheric Administration, cooperative agreement #NA17RJ1226.

Coral Reef Information System (CoRIS): A One Stop Shop for Coral Information

K. Logan[1], M. Newlin[1]

1) National Oceanic and Atmospheric Administration, Silver Spring, MD

Abstract. As a coral reef ecosystem manager, one may be overwhelmed with the range of threats encountered on a daily basis. "How do I diagnose coral diseases?" "Which invasive species may inhabit my reef area?" Scientists and students may also find themselves perplexed over the answers to these same questions. "What is being done to combat these issues?" "Where can I find discussions on coral related topics?" The answers to these questions, and many more, may be found in the National Oceanic and Atmospheric Administration's (NOAA's) Web-enabled Coral Reef Information System (CoRIS). CoRIS data discovery tools provide access to metadata, data, and information from the NOAA Coral Reef Conservation Program (CRCP) and other coral reef projects. CoRIS offers original essays that describe coral biology and physiology, reef structure, and types of reefs, among other topics. The CoRIS Library enables searching and browsing through a growing collection of NOAA's coral ecosystems-related publications, reports, Web sites, educational materials, and digital images. One of the most popular features of CoRIS, the Glossary, defines thousands of terms used in coral reef science and management. Whatever your coral reef data and information needs may be, you can begin your search at the CoRIS website.

Key Words: Coral Reef Conservation Program, Metadata, Data.

Introduction

Destructive fishing practices, increases in sea surface temperatures, habitat destruction, diseases, and invasive species: such are the trials and tribulations in the life of a coral reef. The world's coral reefs are threatened and in decline. It is estimated that 10 percent are now beyond recovery, 30 percent are in their critical stages and may die in the next 10-20 years, and 60 percent may die by the year 2050 (USCRTF 2000).

As a coral reef ecosystem manager, one may be overwhelmed with the range of threats encountered on a daily basis. "How do I diagnose coral diseases?" "What are others doing about habitat destruction so that I can learn from their work?" "Which invasive species may inhabit my reef area?" Scientists and students may also find themselves perplexed over the answers to these same questions. "What is being done to combat these issues?" "Where can I find discussions on coral related topics?" The answers to these questions, and many more, may be found in the National Oceanic and Atmospheric Administration's (NOAA's) Web-enabled Coral Reef Information System (CoRIS).

Background

In 1998, the Presidential Executive Order #13089 was issued to preserve and protect U.S. coral reef ecosystems, and the United States Coral Reef Task Force (USCRTF) was established. In turn, NOAA formed the Coral Reef Conservation Program (CRCP) to guide NOAA's coral efforts.

The USCRTF created the National Action Plan to Conserve Coral Reefs, which called for Web-enabled access to Federal agency coral data and information. In response, the CRCP and NOAA's National Oceanographic Data Center developed and maintain the Web-based CoRIS.

CoRIS is designed to provide a single point of access to NOAA data and information for the management and preservation of the United States' coral reefs. The data and information are primarily derived from NOAA's CRCP. Other goals of CoRIS are to meet the information needs of NOAA managers in the preparation of biennial assessments on the status and trends in U.S. coral reef ecosystem conditions, support NOAA's contribution to the USCRTF National Action Plan to Conserve Coral Reefs, and to facilitate archiving and preserving NOAA's coral reef data and information.

Features

CoRIS provides access to over 18,000 coral ecosystem data and data products by way of more than 2,000 metadata records through the "Discover NOAA's Data" section. Users can access the information in several ways:

1) a Google-Maps based search (Fig. 1) which allows users to search for data and information by geographic

area or by specific data types (such as aerial photos, satellite imagery, habitat maps, reef locations, etc.);
2) a Regional Portal search (Fig. 2) which provides access to all available CoRIS data and information by searching specific regions;
3) a text-based search; and,
4) a metadata browse page which provides a list of all available data from the Web site.

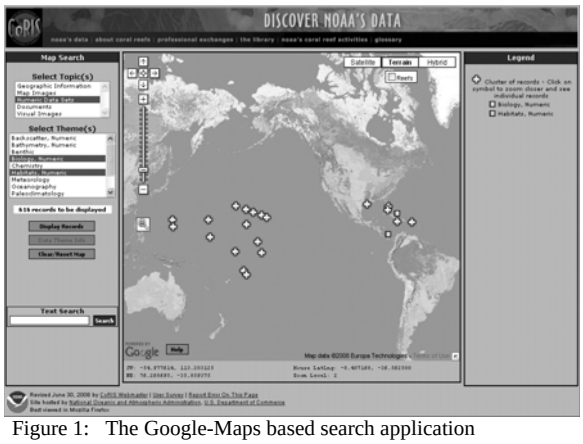

Figure 1: The Google-Maps based search application

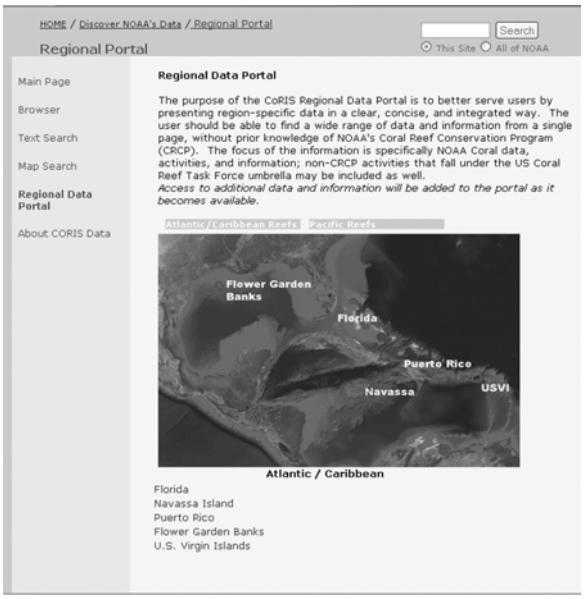

Figure 2: The Regional Portal Search

CoRIS houses a Library collection of over 1,500 publications, reports, journal article citations, Web sites, and more. CoRIS provides direct links to such reports as:

- the "NOAA's Coral Reef Ecosystem Research Plan for Fiscal Years 2007 to 2011" (Puglise and Kelty 2007)
- the "Reef Manager's Guide To Coral Bleaching" (Marshall and Schuttenberg 2006)
- "The State of Deep Coral Ecosystems of the United States: 2007" (Lumsden et al. 2007)
- "The State of Coral Reef Ecosystems of the United States and Pacific Freely Associated States: 2008" (Waddell and Clarke 2008)

Users can search the Library collection, including NOAA Central Library coral ecosystem publications, through a simple and advanced text search, as well as specific browse lists, for available publication information. There are also direct links to the NOAA Photo Library, and both NOAA and non-NOAA coral related Web sites.

CoRIS also provides access to a collection of coral reef essays on a variety of topics including coral biology, deep water corals, coral diseases, and more. There are also ecosystem essays on areas such as the Northwestern Hawaiian Islands and Navassa, and a collection of professional exchanges on pressing coral topics and issues. CoRIS also has an illustrated glossary containing over 5,000 coral ecosystem related terms, as well as information and links to other coral reef activities throughout NOAA.

Some of the types of data and information available from CoRIS include:

- *in situ* biological, chemical, geological, and physical environmental data collected by divers, remotely operated vehicles, moored buoys, current meters, and other types of oceanographic instruments
- Advanced Very High Resolution Radiometer sea surface temperature products and other remotely sensed imagery products
- coastal aerial photographs
- paleoclimatology data derived from coral core analyses
- nautical charts and tidal data
- coastal bathymetry
- digital video and photographs
- benthic habitat maps
- coral bleaching reports

All of the CoRIS search engines rely on metadata files that describe collections of data sets and products. Metadata provide descriptions of the data, when and where the data were collected, who collected the data, direct links to the data when available, and how to obtain a copy of it. Metadata descriptions use the format for the Content Standard for Digital Geospatial Metadata set by the Federal Geographic Data Committee (FGDC 1998), as well as the standards of the National Biological Information Infrastructure for descriptions of biological data sets containing taxonomic names for organisms (FGDC and USGS 1999). To support the data and information discovery process, CoRIS uses a set of standardized keywords to describe thematic topics, geographic areas, and taxonomic names of organisms.

Conclusion

The NOAA Coral Reef Information System provides access to coral reef ecosystem data and information through a variety of discovery and access tools in order to help managers, researchers, students, and others to better protect and preserve the world's coral reef ecosystems. CoRIS has a wealth of data, information, and other resources to offer. Whatever your coral reef data and information needs may be, you can begin your search at the CoRIS website (CoRIS 2008).

Biological and physical characteristics of a mesophotic coral reef: Black Jack reef, Vieques, Puerto Rico

S. Rivero-Calle[1], R.A. Armstrong[1], F.J. Soto-Santiago[1]

1) University of Puerto Rico, Department of Marine Sciences, Mayagüez, Puerto Rico

Abstract. For six decades Vieques Island was used for US Navy military activities. While several studies have addressed the possible impact on shallow coral reefs, mesophotic reefs (30-100 m deep) have been largely overlooked. This study provides an extensive baseline qualitative and quantitative characterization of Black Jack Reef including variations in the light attenuation coefficients, which serve as a proxy for changes in water quality. Operational limitations due to depth were solved using the Seabed Autonomous Underwater Vehicle (AUV). This AUV specifically designed for benthic surveys, was used to obtain two perpendicular phototransects covering a total of 5km at depths ranging 30-51 m. Mean live coral cover was 32% with *Montastraea* and *Agaricia* as the dominant genera. Very low levels of bleaching or diseases were found. Sponges were present in both transects with an average cover of 7-9%. The most common sponges were *Amphimedon compressa, Aiolochroia crassa, Agelas*, *Aplysina* and *Xestospongia muta*. Gorgonians and Black corals were present in very low abundance. Extensive areas of rhodolith beds were found. Turbidity does not appear to be a determinant factor at Black Jack Reef.

Key words: mesophotic reefs, Seabed AUV, Vieques

Introduction

The islands of Vieques and Culebra are in the northeastern Caribbean within the Puerto Rico- Virgin Island geological platform. Culebra and Vieques were used for US Navy military activities for many decades. Military activity at Vieques began in the 1940's and has just recently ended with the hand over of military owned lands to the Department of the Interior in May of 2003, becoming part of the Vieques National Wildlife Refuge. Vieques coral reefs are considered among the best in Puerto Rico in terms of live coral cover (greater than 30%) (García-Saís et al. 2001, 2004).

During the military occupation much of its area was closed to the public and little scientific research was permitted. Ecosystem damage has long been recognized by Rogers et al. (1978) and military debris can still be seen today (Riegl et al. 2008). However, decline in coral cover has been attributed to hurricanes (Antonius and Weiner 1982), sea surface temperature (Dodge 1981), turbidity (Deslarzes et al. 2006) or more recently the combination of hurricanes and diseases (Riegl et al. 2008). Riegl et al. 2008 concluded that the impact of bombing in the coral reef was negligible and, even more, suggested that the military occupation prevented further damage derived from land-based development.

In 2001 García-Saís et al. performed a baseline study outside the shooting range followed by monitoring in 2004. Deslarzes et al. (2006) compared Vieques and Culebra concluding that Vieques reefs were in worst condition. Bombing activities in Culebra stopped in 1975. Riegl et al. (2008) studied the geomorphology and coral assemblage structure and found that Vieques reefs are comparable to those of St. Croix, US Virgin Islands. Recent reef mapping efforts in these areas have been carried out by Hernandez-Cruz et al. (2006), Kendall and Eschelbach (2006), and Monaco et al. (2001). Although shallow reefs (upto 15 m depth) have received much attention, especially within the US Navy shooting range, no studies have taken deep reefs into account. Deeper reefs are typically unaffected by hurricanes or high sea surface temperatures (Riegl and Piller 2003; West and Salm 2003). Practically all mesophotic (30-100 m) coral reef communities of Vieques have not been properly characterized (García-Saís et al. 2008). The only exception to this has been Black Jack Reef (30-40 m depth), which was described in 2001 and characterized in 2004 using five 10 m transects (García-Saís et al. 2004). Further exploratory surveying, mapping, and monitoring of Vieques deep coral reef systems is needed (García-Saís et al. 2008). On the other hand, none of the previous studies has detailed the sponge species found considering they could be an important reef component.

The transparency of the surrounding waters and the relatively wide insular platform of Vieques create the potential for numerous mesophotic reefs, especially in

the south. However, operational limitations due to depth require the use of new technologies for fast and safe assessment and monitoring. Satellite and airborne techniques are limited to the first 20 m and submersibles are generally too costly for most monitoring programs. The Seabed Autonomous Underwater Vehicle (AUV) was specifically designed for benthic surveys up to 2000m deep. It has proved succesful in previous studies in southwestern Puerto Rico (Armstrong et al. 2002; Singh et al. 2004) and in the Hind Bank Marine Conservation District (MCD), USVI (Armstrong et al. 2006).

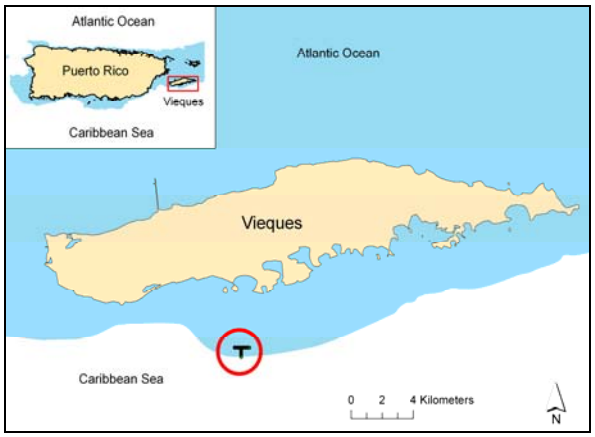

Figure 1. General location of Vieques and transects. The red circle south of the island shows relative position of the two perpendicular transects. Blue shade corresponds to the insular platform.

The aim of this work is: 1) to provide a more extensive (5 km) baseline description of mesophotic reef areas in Black Jack Reef, southern Vieques (Fig.1), 2) to generate a qualitative and quantitative evaluation of coral and sponge taxa, and 3) to describe patterns of light attenuation variation as a proxy for changes in water quality parameters.

Material and Methods

The Seabed AUV is composed of two cylindrical body sections fixed together, coupled with three thrusters and equipped with: a Pixelfly 1024 x 1280 pixel resolution CCD camera with 12 bits of dynamic range, a 150 Ws strobe, a paroscientific depth sensor and a 300 kHz Acoustic Doppler Current Profiler (ADCP). This AUV was designed to be hover capable and to maintain a constant direction and altitude from the bottom. More information on Seabed components and sensors, control and navigational systems can be found in Singh et al. (2004).

During November 2004 we used the Seabed AUV to obtain two long phototransects at Black Jack Reef in southern Vieques Island (based on García-Saís et al. 2004) covering a total of 5 km at depths ranging from 30 to 51 m.

The AUV digital images were analyzed using Coral Point Count with Excel extensions (CPCE, Kohler and Gill 2006). Five major benthic groups were considered: scleractinians, sponges, black corals (Antipatharians), algae and gorgonians. Benthic organisms were identified to the lowest possible taxon and special attention was given to scleractinian and sponge species as well as type of substrate. Coral cover was estimated using the random point method. Since there were large areas of unconsolidated sediment with encrusting algae and cyanobacteria as well as large extensions of rhodolith beds and our main interest was focused on patterns of distribution of benthic mega-invertebrates, bare substrate, algae and cyanobacteria were grouped under the general category: SUBSTRATE+ALGAE+CB (see Figs. 2, 3).

Temporal variation in the light attenuation coefficient (K490) was obtained from MODIS Aqua level 3 imagery at 4 km resolution, producing monthly averages from 2003 to 2008.

During April 2008, salinity, temperature and light attenuation profiles were measured in Vieques using a Satlantic Hyperpro spectroradiometer.

Results

Two phototransects from southern Vieques were analyzed: transect 1 was 1 km long and oriented from north to south (starting at 18.0507N, 65.4633W), while transect 2 was 4 km long and oriented east to west (18.0558N, 65.4586W). A total of 894 and 1540 images, respectively were produced at a constant altitude of 2.5 m from the bottom. Depth ranges were 30-51 m for the North-South transect and 34-43 m for the West-East transect.

The North-South transect (Fig. 2) was composed of about 30% coral reef (defined as areas with a certain structural complexity and some coral cover) and the other two thirds consisted of an extensive rhodolith bed with a few sponges, gorgonians and corals sparsely distributed. The West-East transect (Fig. 3), however consisted of 75% coral reef with 60% coral cover in some areas at 36 m depth. Only the most western part had sand or fine sediment (data not shown). No military debris was identified in any of the phototransects. A substantial amount of rubble and bare substrate could be seen at the southern part of the North-South transect.

At least 36 species of sponges and 17 species of corals were identified. The *Montastraea annularis* species complex, *M. cavernosa* and *Agaricia* spp. were the most common corals found. The most common sponges were *Amphimedon compressa, Aiolochroia crassa, Agelas* sp., *Aplysina* sp. The barrel sponge (*Xestospongia muta*) was also abundant.

Mean live coral cover at reefal sites was lower in the North-South transect (3-11%) than in the West-East transect (10-48%) (Figs. 2 and 3, respectively). In the North-South transect (Fig. 2), the non-reefal part of the transect was composed of a rhodolith bed (98% cover), hardly any macroalgae, some sparse sponges (2% cover) and corals (less than 1% cover). Gorgonian cover was quite low (6 % cover) at reefal sites, and was nearly zero in the non-reefal zone. Black coral cover was less than 1% in both transects.

The West-East transect (Fig. 3), shows remarkable high average mean coral cover at the end of the transect (48%) with an average of 25% live coral cover for the entire 4 km transect. Algae and bare substrate covered an average of 64% of the substrate. Sponges had an average cover of 9%, reaching 20% for the western part of the transect. Gorgonian cover however was less than 1% throughout the entire transect. The westernmost part of the transect consisted of large areas of sand/sediment accumulation.

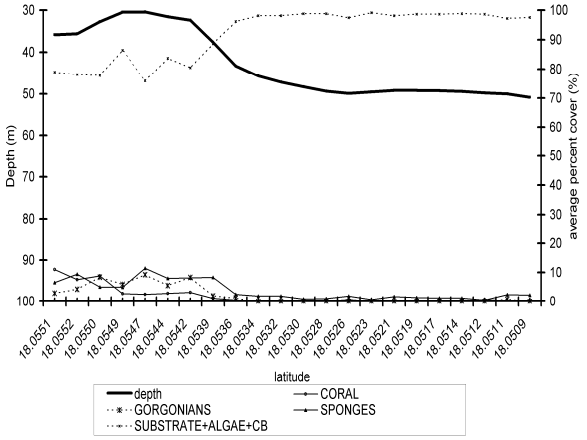

Figure 2. North-South transect average percent cover of each category (obtained every ten frames).

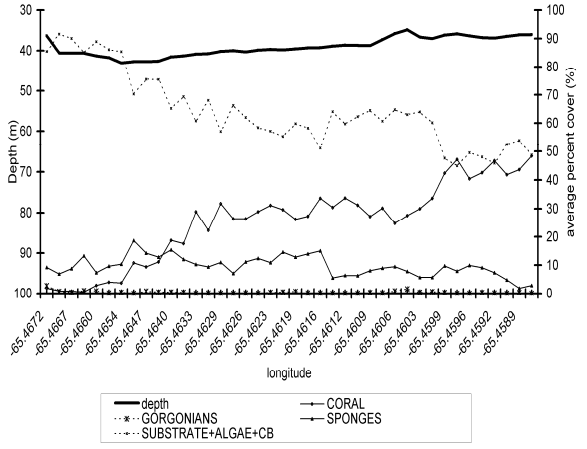

Figure 3. West-East transect average percent cover of each category (obtained every ten frames).

The relationship between coral cover and depth show a negative correlation for both transects (Fig.4, 5), indicating that coral cover decreases with increasing depth. The relationship (R^2) is stronger for the West-East transect (0.33 vs. 0.25).

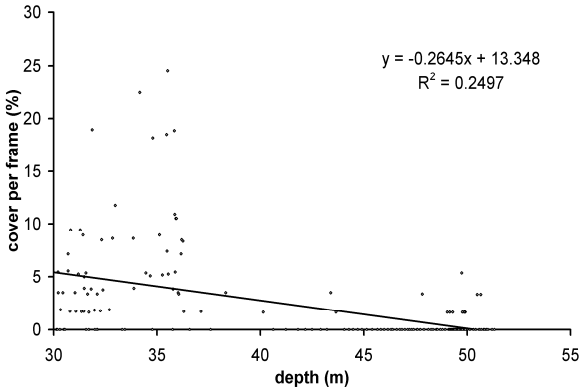

Figure 4. Live coral cover percentage per frame vs. depth in the North-South transect.

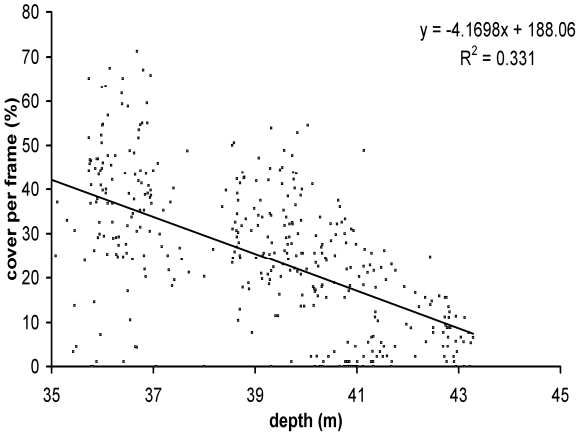

Figure 5. Live coral cover per frame vs. depth in West-East transect.

Profiles of temperature and salinity, which were measured every meter from the surface to 45m depth, ranged from 25.8-26.2 ºC, and 37-38.5 psu, respectively. The Ed PAR (downwelling irradiance) profile (Fig. 6) demonstrates the transparency of these waters with 10% of the surface Ed present at 39 m. The surface Ed is approximately 1500 $\mu W/cm^2/nm$. Satellite derived K490 show little variation from 2003 to 2008, with average values ranging from 0.03 to 0.04 m^{-1} (Fig. 8). Higher values were present in July 2006 (over 0.05 m^{-1}) whereas April 2007 had particularly low values at 0.02 m^{-1}.

Southern Vieques waters are very clear throughout the year although they become slightly more turbid during the rainy season (July to December). Gaps in June are due to high cloud cover in the satellite images.

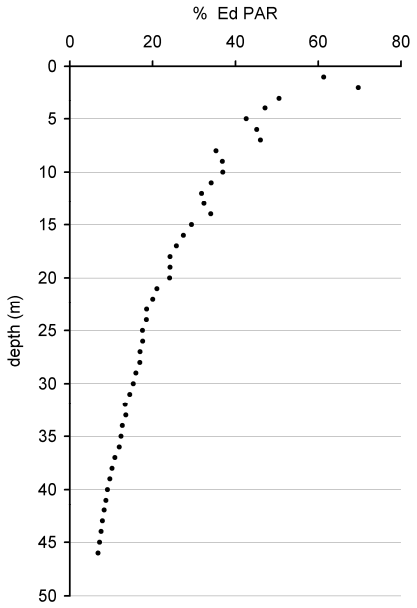

Figure 6. Light attenuation with depth. Percentage of Photosynthetically Available Radiation (PAR 400-700nm) per depth in South Vieques during April 2008.

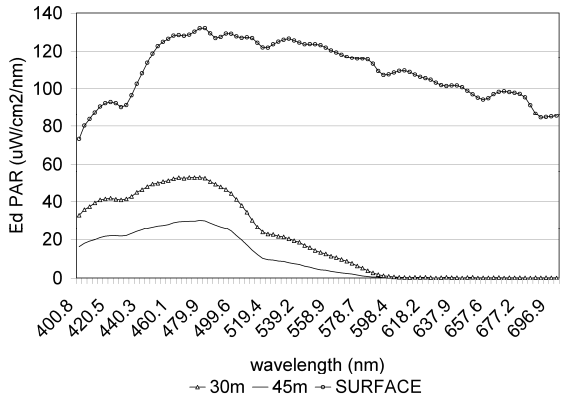

Figure 7. Downwelling PAR irradiance spectra at surface, 30 and 45 meters deep in South Vieques during April 2008.

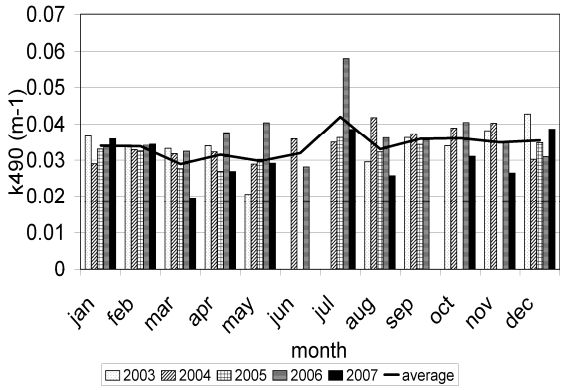

Figure 8. Temporal variation of light attenuation coefficient at 490 nm (K490). Average value per month per year from 2003-2008 calculated using MODIS Aqua data south of Vieques at 18.05N, 65.46W.

Discussion

The two AUV transects provided detailed information on benthic cover and geomorphology of a Vieques mesophotic coral reef complex. In most cases, the AUV imagery resolution was adequate to identify organisms to at least genus level if not species level, for both corals and sponges as well as other non-motile mega-invertebrates. These mesophotic reefs appear not to be as extensive as those described for the Hind Bank MCD (17 km east of Vieques) by Armstrong et al. (2006) with mean live coral cover of 32% as opposed to 43%, respectively. Coral cover values are similar to the 28.8% reported at Black Jack Reef by García-Saís et al. (2004). In all three cases, *Montastraea annularis* species complex dominated live coral cover.

Sponges were continuously present in both transects with an average cover of 7-9% and up to a maximum of 26.9% at the western part of West-East transect at a depth of 43 m. Average sponge cover values are similar but slightly higher than the 5.8% reported at Black Jack Reef by García-Saís et al. (2004) and 3.8% at the Hind Bank MCD (Armstrong et al. 2006). *Cliona* was not the dominant species as in the MCD where it accounted for 96% of the sponges found (Armstrong et al. 2006). The morphology of the most frequent sponges found was usually tube or rope-like, except for the massive *Xestospongia muta*, and a few encrusting or spherical-forms.

Gorgonians showed very low cover in both transects, similar to the Hind Bank MCD (Armstrong et al. 2006) and to what was reported at Black Jack Reef by García-Saís et al. (2004). Black corals were present in very low abundance (less than 1%) coinciding with García-Saís et al. (2004).

The distribution of live coral cover appeared to be related to the geomorphology and weakly related to depth. Coral cover was higher in areas of topographic relief. However, sponges were also present over unconsolidated sediments due to their faster growth rates. This pattern was more evident in West-East transect where the western side had an elevated dense coral reef (up to 50% live coral cover) whereas the eastern side accumulated sand and had sparse coral colonies and sponges.

Very low levels of coral disease or bleaching could be seen in the AUV images. This agrees with Armstrong et al. (2006) results from similar depths at the MCD.

Water quality, at least in terms of turbidity, does not appear to be a determinant factor at Black Jack Reef, contrary to what Deslarzes et al. (2006) suggested for Vieques reefs. This is to be expected since Black Jack Reef is deeper and farther from the coast. As in the MCD, most corals presented a plate

shape in response to the low-light environment at these depths. As in shallow water reefs, increases in light attenuation could serve as a precursor of change in mesophotic reefs, where incident irradiance levels could be near the lower limit for coral growth.

Since Black Jack Reef is outside the bombing range, military debris was not expected and was not observed in the AUV imagery. Additional transects within the bombing range will be required to ascertain the possible impact of past military activities in both shallow and deep reef areas.

Colored Dissolved Organic Material Increases Resiliency of Coral Reefs by Controlling Exposure to UVR

L. Ayoub, P. Hallock, P. Coble

College of Marine Science, Univ. South Florida, 140 7th Ave. S., St. Petersburg, FL 33701, USA

Abstract. Although mass coral bleaching events are generally triggered by high seawater temperatures, experiments have demonstrated that corals and reef-dwelling foraminifers bleach more readily when exposed to high energy, short wavelength solar radiation (blue, violet and ultraviolet [UVR]: λ ~ 280 - 490 nm). In seawater, colored dissolved organic matter (CDOM), also called gelbstoff, preferentially absorbs these shorter wavelengths, which consequently bleach and degrade the CDOM. Alteration and destruction of watershed and coastal wetlands have reduced natural sources of CDOM that are tidally flushed into reefal waters. We have measured absorption of UVR and UV irradiance at various reefs in the Florida Keys that differ in distance from shore and the degree of anthropogenic development of the adjacent shoreline. Our results show that reefs associated with intact shorelines tend to be exposed to lower intensities of UVR than reefs associated with developed shorelines. Absorption due to CDOM at 320 nm (a_{g320}) was less variable at reefs associated with intact shorelines, and higher at inshore reefs compared to offshore reefs. UVR is attenuated more quickly at inshore than offshore, clear-water reefs at similar depths. Spectral slope of a_g, S, was generally greater at offshore sites, indicating a higher degree of photobleaching of CDOM.

Keywords: ultraviolet radiation, coral reefs, absorption coefficient, attenuation coefficient, CDOM

Introduction

Corals worldwide have been declining since the 1970's and the prognosis for the future is not improving (Birkeland 2004; Hoegh-Guldberg et al. 2007). Coral bleaching has become a worldwide phenomenon, and the frequency and intensity of bleaching is increasing (Hoegh-Guldberg 1999; Wilkinson 2002). While the relationship between coral mass-bleaching events and elevated sea-surface temperature (SST) is well established (Hoegh-Guldberg 1999), increasing numbers of studies are revealing that light plays a vital role in coral bleaching. For example, Lesser and Farrell (2004) found that corals do not bleach in the absence of light. Low wavelength ultraviolet radiation (UVR) and blue light can stimulate production of reactive oxygen species causing gene mutation and other damaging consequences to marine invertebrates (Lesser 2006; Levy et al. 2006).

Mass bleaching events typically occur when sea conditions are unusually calm (e.g., Fabricius et al. 2004) and thermal bleaching appears to be caused by photoinhibition and photodamage to photosystem II of the zooxanthellae (e.g., Lesser and Farrell 2004; Smith et al. 2005). The fact that clouds or direct shading can reduce bleaching in corals provides more evidence for the necessary role of light (e.g., Mumby et al. 2001; Fabricius et al. 2004). More recent studies are linking coral disease and photooxidative stress (Lesser 2006).

UVR specifically has been shown to cause DNA damage, DNA mutations or cell death in marine organisms such as corals (Shick et al. 1996). Although it is generally thought that UVR attenuates quickly, some natural water bodies are characterized by high transparency to UVR (Gleason and Wellington 1993).

Pure water absorbs minimally at wavelengths below 490 nm, thus attenuation of the shorter wavelengths of light is primarily due to dissolved and particulate matter (Kirk 1996). Light absorption by colored dissolved organic matter (CDOM) is highest at the shortest wavelengths and exponentially decreases with increasing wavelength. Moreover, the absorption of high-energy radiation causes bleaching and degradation of CDOM (Zepp et al. 2008). Spectrally, photobleaching of CDOM increases with decreasing wavelength from 500 to 280 nm, with the most effective photobleaching occurring in the UV-A region (320 – 400 nm) (Osburn et al. 2001). While an increase in rates of CDOM breakdown may not be biologically significant in turbid, CDOM-rich waters, it may be a major reason why corals in clear waters are reportedly more susceptible to bleaching (e.g.,

West and Salm 2003) and possibly also to diseases that are not directly related to pollution. For example, as a consequence of the 4% global reduction in stratospheric ozone following the Mt. Pinatubo eruption (Randel et al. 1995), the resultant approximately 8% increase in UV-B reaching the sea surface (Schick et al. 1996) could have increased the rate of CDOM degradation by as much as 24% (Zepp et al. 2003). Other studies estimate a lower percentage change, for example, a 25% increase in UV-B results in a 10% increase in photobleaching according to studies on temperate lakes (Osburn et al. 2001).

As a defense against UVR, corals and other aquatic organisms produce UV-absorbing pigments called mycosporine-like amino acids (MAAs) (Shick et al. 1996). Maximum absorption for MAAs occurs between 305 and 360 nm. Thus, the presence of MAAs can indicate photic stress (Morrison and Nelson 2004).

Exposure to UVR has been increasing in recent decades due to stratospheric ozone depletion, resulting in increased photobleaching of CDOM and, in turn, deleterious effects on marine biota (Fig. 1). We postulate that CDOM is protecting inshore patch reefs from exposure to the most extreme solar radiation and damaging effects of photooxidative stress.

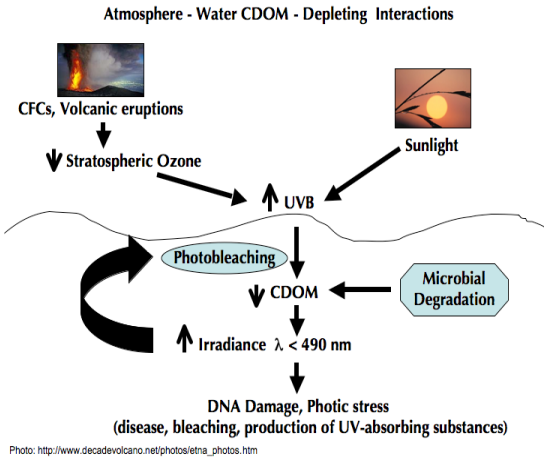

Figure 1. Atmospheric, optical, and biological factors affecting CDOM absorptivity and related biological effects (after Morris and Hargreaves 1997; Zepp et al. 2008).

Material and Methods

In late May, early July and late September 2004, and early May and mid-July 2005, water samples and *in situ* optical data were collected at several reefs in the upper and middle Florida Keys. In addition, in September 2004, absorption due to CDOM (a_g) was measured along a transect (red arrow in Fig. 2) from offshore at 75 m depth, shoreward to 50 m and 25 m depths, inshore to Carysfort and Algae Reefs, and finally within a mangrove-lined canal in John Pennekamp State Park. In summer 2006 and 2007, sampling sites included inshore and offshore coral reefs in the Upper, Middle and Lower Keys that lie within the Florida Keys National Marine Sanctuary (FKNMS) and are part of the Coral Reef Evaluation and Monitoring Program (CREMP) (Fig. 2).

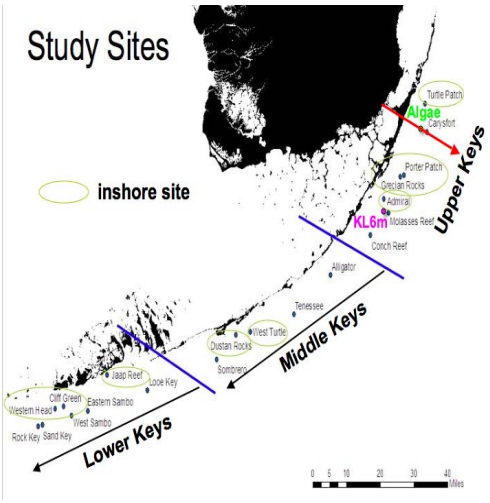

Figure 2. Study sites in the Lower, Middle and Upper Florida Keys included offshore reefs and inshore (patch) reefs that differ in degree of development of associated shoreline. In 2006 and 2007, study sites also included inshore and offshore CREMP study sites in the Lower, Middle and Upper Florida Keys (image collaboration with A. Ramirez).

Total absorption can be partitioned into absorption due to dissolved material, a_{CDOM}, particulate material, a_{PM}, and pure water, a_w (Kirk 1996). Using measured a_{CDOM} and a_{PM}, and published values of a_w (Morel et al. 2007):

$$a_t(\lambda) = a_{CDOM} + a_{PM} + a_w \quad (1)$$

In natural systems, light is not collimated but diffuse. Measuring irradiance consistently within 2 hours of solar noon minimizes the effect of sun angle and thus pathlength on light attenuation. Total attenuation is due to scattering as well as absorption. Scattering is negligible compared to absorption for this study (Ivey, unpubl. data). Thus, the diffuse attenuation coefficient of downwelling irradiance (K_d) can be estimated from total absorption (Kirk 1996):

$$K_d = a_{CDOM} + a_{PM} + a_w \quad (2)$$

Water samples were collected from the subsurface (~ 0.5 m) and at the depth of coral growth by SCUBA divers or using Niskin bottles. After filtration of water samples, samples were frozen and transported back to the lab, where spectral absorption (300-800 nm) for CDOM ($a_g(\lambda)$) was measured according to the method described in Mueller and Fargion (2002) and $a_{PM}(\lambda)$ was measured according to Mitchell (1990) using a UV-Visible spectrophotometer (Perkin Elmer Lambda 18 or Hitachi U 3300). Spectral absorption due to detritus,

a_d (λ), was determined by methanol extraction of pigments and subtracted from $a_{PM}(\lambda)$ to determine spectral absorption due to phytoplankton, a_{phi} (λ):

$$a_{phi}(\lambda) = a_{PM}(\lambda) - a_d(\lambda) \quad (3)$$

(Kirk 1996). Relative MAA expression was determined using the method of Morrison and Nelson (2004).

In July 2004, incident solar irradiance reaching the sea surface was measured using a LiCor - 1800 Spectroradiometer (280-850 nm) at a nearby land site at 10-20 minute intervals from 8:30 am – 6:30 pm daily. Intensity of irradiance reaching the benthos was calculated from measurements of in-lab absorption a_t (λ) and the *in situ* incident downwelling irradiance E_{d0} (λ) according to eqn. (3) and:

$$E_{dz}(\lambda) = E_{d0}(\lambda) * e^{-Kd(\lambda)* z} \quad (4)$$

where z represents depth in meters (Kirk 1996). After July 2005, K_d was calculated from *in situ* underwater downwelling cosine irradiance ($E_d(\lambda)$) measured at 305, 330, 380 nm (10 nm wavebands, recorded at maximum wavelength minus 5 nm) and PAR (integrated from 400 – 700 nm) using a BIC (Biospherical Instruments, Inc.) radiometer.

Differences in a_g, K_d, spectral slope S, and relative MAA expression were determined using one-way ANOVA statistical tests.

Results

Absorption due to CDOM decreased going offshore from mangroves to inshore reefs, offshore reefs and finally blue water (Fig. 3), exhibiting the progressive dilution of land-sourced CDOM.

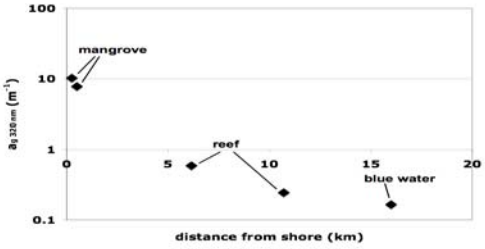

Figure 3. Transect of absorption due to CDOM at 320 an ($a_{g\,320}$). $a_{g\,320}$ decreased going from mangrove canals in John Pennekamp Park to inshore and offshore reefs to offshore blue water.

Downwelling UV irradiance at 320 nm at depth = 6m ($E_{d6m\ 320nm}$), modeled from a_{t320} and incident irradiance (E_{d0}), was significantly higher at reefs associated with developed shoreline, such as KL6m ($E_{d6m\ 320nm}$ = 0.01 - 0.084 W/m^2) than at reefs offshore from extensive mangrove shoreline, such as Algae Reef ($E_{d\ 320nm}$ = 0.008 – 0.057 W/m^2) ($p < 0.05$, Fig. 4).

Over the period of sampling, 2004 – 2007, the average contribution of absorption due to CDOM, a_g, to total absorption, a_t, increased with decreasing wavelength, ranging from 60% at 380 nm to over 90% at 305 nm. Thus, CDOM is the major attenuator of UVR. Over the course of each summer a_g/a_t typically decreased, likely due to photobleaching of CDOM (Fig. 5). The observed increase in a_g/a_t from May to July 2005 may be due to the higher rainfall which occurred in June and July, causing greater runoff and thus increased CDOM over the reef (http://www.ncdc.noaa.gov/oa/climate/research/monitoring.html#ustempprcp).

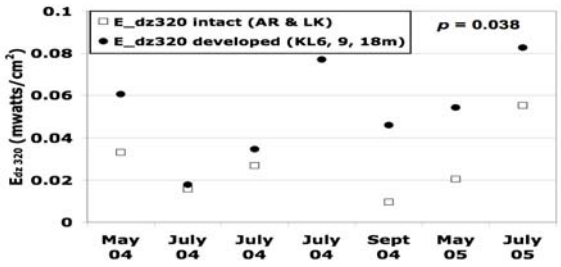

Figure 4. $E_{d6m\ 320}$ was significantly lower at intact shoreline-associated reefs compared to developed shoreline-associated reefs ($p < 0.05$).

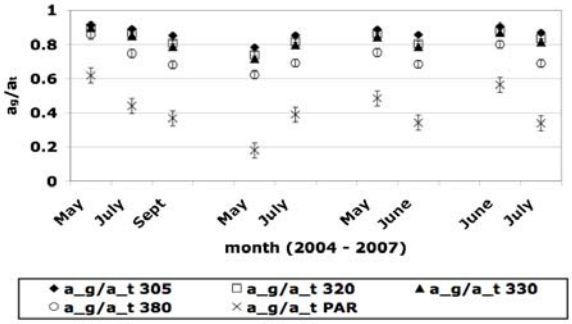

Figure 5. Average relative contribution of a_g to a_t in the UV at 305, 320, 330, 380 nm ranged from 62% at 380 nm to 91% at 305 nm and from 18 – 62 % for PAR. Average a_g/a_t typically declined at all wavelengths as the summer progressed.

Comparing a_g between inshore and offshore reefs, a_g was significantly higher at inshore reefs at all wavelengths (e.g., a_{g320}, Fig. 6, p = 0.0086). Concurrently, K_d measured *in situ* using a BIC radiometer was significantly higher at inshore reefs (ex: $K_{d\ 330}$, Fig. 6, Table 1, p = 0.00297). Differences in spectral quality were also observed: excepting discrepancy from this trend at 305 nm due to immeasurably low irradiance intensities, the difference in K_d between inshore and offshore reefs decreased with increasing wavelength, with the p value for $K_{d\ PAR}$ an order of magnitude higher than for $K_{d\ UV}$ (Table 1). Thus, difference in water transparency between inshore and offshore reefs was greater for UVR than for PAR.

Both a_g and K_d, two independent measures of UV transparency, illustrate that coral reef biota are exposed to lower intensities of UV irradiance at

inshore reefs compared to offshore reefs in the Florida Keys.

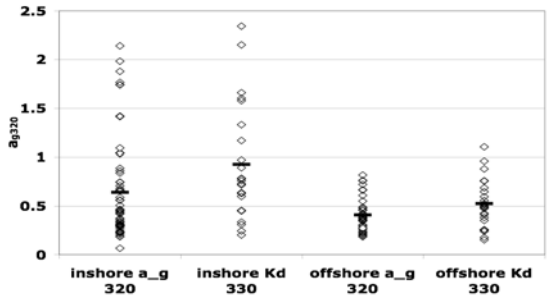

Figure 6. Absorption due to CDOM at 320 nm ($a_{g\ 320}$) was significantly higher at inshore reefs (n = 58, average = 0.64) than offshore reefs (n = 38, average = 0.41) (p < 0.01). The attenuation coefficient of downwelling irradiance at 330 nm, $K_{d\ 330}$, was significantly higher at inshore reefs (n = 23, average = 0.928) than offshore reefs (n = 25, average = 0.524) (p < 0.005). Dashes represent averages.

	average		range		std dev		
K_d (λ)	in	off	in	off	in	off	p
$K_{d\ 305}$	1.40	0.83	0.32 – 1.30	0.27 – 1.83	0.93	0.38	0.008
$K_{d\ 330}$	0.93	0.52	0.20 – 2.15	0.24 – 1.10	0.59	0.24	0.003
$K_{d\ 380}$	0.42	0.25	0.13 – 0.90	0.066 – 0. 56	0.25	0.12	0.003
$K_{d\ PAR}$	0.23	0.18	0.07 - 0.32	0.025 – 0.49	0.06	0.09	0.039

Table 1. Statistical data comparing K_d between inshore and offshore reefs. The difference in K_d between inshore and offshore reefs was greatest for 330 and 380 nm, and least for PAR (in = inshore, off = offshore).

Relative expression of MAAs varied inversely with $a_{g\ 320}$ (Fig. 7) and was higher and more variable at reefs associated with developed shoreline (a_{phi_325} /a_{phi_350} = 1.3 – 2.7, CV = 30%) than at reefs associated with intact shoreline (a_{phi_325} /a_{phi_350} range = 1.03 to 1.2, CV = 6%), (p < 0.05).

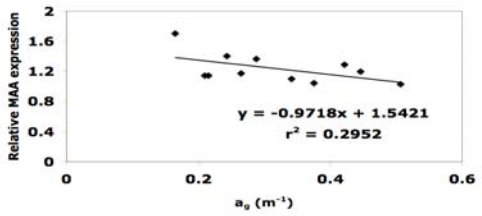

Figure 7. Relative expression of MAAs varied inversely with $a_{g\ 320}$ (slope = -0.97) for intact and developed reefs in 2004 – 2005.

Spectral slope of a_g in the UV, $S_{(280\ –\ 312\ nm)}$, was significantly higher at offshore sites (avg. = 0.030, std. dev. = 0.003) compared to inshore sites (avg. = 0.027, std dev. = 0.004) (p = 0.001). S is an indicator of photobleaching of CDOM (Del Vecchio and Blough 2002). Thus, in addition to higher exposure to UVR (Fig. 6), CDOM at offshore reefs was more highly photobleached.

Discussion

Though traditionally it has been thought that corals require clear water for photosynthesis, recent trends show that the clearer water reefs are experiencing higher rates of coral decline. In the Florida Keys, distance from shoreline as well as shoreline quality may influence reef health as recent declines in percent coral cover and coral biodiversity have been greater at offshore reefs than inshore reefs (Somerfield et al. 2008) and coral-lesion recovery rates are higher at inshore (patch) reefs near intact mangrove shoreline than developed shoreline (Fisher et al. 2007). Inshore reefs may be closer to seagrass beds, mangroves, wetlands, and other terrestrial sources of CDOM. Our work shows that differences in water transparency, and the resulting spectral differences in solar radiation reaching the benthos, may contribute to different rates of decline in coral cover between inshore patch reefs and offshore shallow reefs.

This study helps to support/explain previous observations in the Florida Keys: 1) lower rates of decline at inshore reefs than offshore reefs (e.g., Somerfield et al. 2008); 2) consistently higher bleaching in larger foraminifers at a reef associated with clearer water (Conch Reef) than at a reef influenced by Florida Bay water (Tennessee Reef) (Williams 2002); 3) occurrence of bleaching in benthic foraminifers (*Amphistegina gibbosa*) in the Florida Keys follows solar cycle, not SST cycle, and increases with increasing UV:PAR (Williams 2002); and 4) higher coral cover, coral-lesion recovery rates and abundances of larger foraminifers at a reef associated with intact shoreline (Algae Reef) compared to a reef associated with developed shoreline (KL6m Reef) (Fisher et al. 2007).

Prior studies also show deleterious effects of UVR on reef organisms. Lab experiments have shown that bleaching in *A. gibbosa* is exacerbated by exposure to blue or UV wavelengths (Williams and Hallock 2004). Studies of bleaching in corals indicate that decline in zooxanthellate photosynthetic capacity follows increase in daylight and precedes temperature peak (Warner et al. 2002), and that UVR and PAR exacerbate supraoptimal temperature effects (Lesser and Farrell 2004). Although MAAs are photoprotective, the energetic cost of MAA production may inhibit growth and recovery from stress (Hoogenboom et al. 2006**)**, and high solar radiation may depress MAA production (Lesser and Farrell 2004**).**

Based on modeled entire water column photobleaching in lakes, photobleaching can cause 0.6 to 1.4% decrease in CDOM light absorption over the timescale of tidal flushing (12 hours) (Reche et al. 2000). Offshore reefs and developed shoreline-associated reefs that do not receive consistent, tidally flushed pulses of CDOM are particularly susceptible to increased UV transparency due to photobleaching of CDOM.

In conclusion, UV irradiance may contribute to photooxidative stress and reef decline in the Florida Keys. Management of shorelines to protect sources of photo-protective CDOM such as mangroves, seagrasses, and wetlands may reduce susceptibility to bleaching in corals.

Abstract. Efficient survey methodologies that provide comprehensive assessment of reef condition are fundamental to coral reef monitoring. Current state-of-the-art techniques in coral reef assessment rely on highly trained scientific divers to measure indices of reef health (e.g., substrate cover, species richness, coral size, coral mortality). First-generation video mosaics were an innovative survey technology that provided large-scale (up to 400 m^2), spatially accurate, high-resolution images of the reef benthos without extensive survey times or a need for scientific divers. Despite these advances, first-generation mosaic products were insufficient for species-level identification of many benthic taxa, thereby limiting the monitoring potential of the technique. A second-generation mosaic survey technology has been developed, which integrates high-resolution still-image acquisition with high-definition video surveys of the reef benthos. These second-generation products have sub-millimeter benthic resolution allowing for species identification of coral colonies (as small as 3 cm), identification of macroalgal genera, and increased information on coral colony health and small scale competitive interactions. This combined survey technology allows users to collect imagery on both a landscape and colony level over 100's of square meters in under an hour of in-water dive time. The resulting product has excellent archive potential and is a superior tool for tracking changes over time.

Key words: Video mosaics, coral monitoring, benthic surveys.

Introduction

Worldwide decline of coral reef communities since the 1970's has prompted the development of numerous reef monitoring techniques at multiple spatial scales. Traditional monitoring methodologies rely heavily on expert scientific divers to measure indices of reef health during field surveys. These methods often result in long dive times and a lack of permanent raw data of the state-of-the-reef at the time of the survey. To address these weaknesses, many monitoring programs now incorporate underwater photography or video into their survey design so that images can be analyzed out of the water to measure metrics such as percent cover and coral colony sizes. Standard underwater video and still imagery often reduce the dive time and expense of reef monitoring, but they provide either a small image footprint or have low resolution thereby limiting their value as complete coral community monitoring tools.

An underwater video mosaic survey technology has been developed to create large (several hundred m^2), spatially accurate, high-resolution video mosaics of reef communities that provide a landscape view of the seabed while minimizing dive-time (usually < 1 hr) (Lirman et al. 2007). Such "landscape mosaics" overcome many limitations of previous survey methods while retaining most of their strengths. Mosaics can be created without trained, expert scientific divers, long dive times, or the use of extensive permanent markers that are normally required for repeated surveys of the same locations. Their high spatial accuracy allows accurate measurements of distances and colony size directly from the mosaics themselves (Lirman et al. 2007).

Over the past four years, landscape mosaics have been used to assess coral reef status (Lirman et al. 2007), hurricane impacts (Gleason et al. 2007), bleaching events, ship groundings, and the status of submerged cultural resources (unpubl. data).

The first-generation landscape mosaics were created from video taken with either a Sony TRV 900 DV camera hand-held by a diver, or a Point Grey Research Flea camera mounted on a Remotely Operated Vehicle. These two camera systems provided spatial resolution ranging from one to four mm/pixel, which was sufficient to identify taxonomic groups, such as stony corals, sponges, gorgonians, macroalgae and sand, but was not fine enough to allow species-level identification in most cases (Lirman et al. 2007). Organisms smaller than 5 cm in diameter were typically not detectable using first-generation mosaic products (Lirman et al. 2007).

The aim of this paper is to describe a second-generation imaging system with improved benthic resolution. This second-generation system was used to survey a permanent study plot at Brooke's Reef, Florida in June 2008. This mosaic was then compared to the first-generation mosaic acquired at this same site in June 2004.

Material and Methods

The use of cameras for benthic habitat mapping has been an active area of research over the last decade. (Negahdaripour and Madjidi 2003; Gracias et al. 2003; Singh et al. 2007). In the present research, the algorithm for creating large scale video mosaics is based on the approach described by Gracias et al. (2003) and Lirman et al. (2007). The first-generation of mosaic processing consisted of four steps using underwater video images. Mosaics were produced by 1) creating an initial estimation of camera motion using feature matching of textured areas between sequential image frames (Lowe 2004; Brown and Lowe 2003), 2) predicting and matching of non-sequential frames, 3) refinement of the camera motion estimation based on using bundle adjustment, and 4) blending of the individual video frames to create a seamless single image of the survey area (Gracias et al. 2006).

This mosaic algorithm requires a high degree of overlap between sequential images to accurately estimate camera motion. In the field, high overlap between images is achieved by using a video camera with a high rate of frame capture (i.e. 30 frames per second, fps). Video cameras, however, have relatively low image resolution (< 1 Megapixel, MP). Therefore high benthic resolution images can only be acquired with these cameras if a very small field of view is maintained during the survey. This is accomplished by maintaining a small distance from the camera to the seabed (typically 40 cm or less). Although in use for some monitoring programs (e.g. Somerfield et al. 2008), this approach does not allow for the 1.5 to 2 m disparity between the benthos and camera normally needed for accurate landscape mosaic processing (Lirman et al. 2007). Current camera technology does not provide a single reasonably priced camera system that can simultaneously capture frames at a high rate with the image resolution necessary for species level identification from 2 m above the bottom.

To overcome the resolution limits of the first-generation mosaic survey technology while maintaining the high frame rate and altitude requirements of the mosaic processing algorithms, a two-camera system was adopted. This second-generation mosaic imaging system combines information from (1) a high-definition video (HDV) camera capable of full video frame rate (30 fps) and (2) a digital still camera capable of acquiring very high-resolution images (10 MP) at low capture rates (1 fps).

The second-generation mosaic imaging system was created using commercially available components, including a Nikon D200 10 MP Digital SLR camera and Ikelite underwater housing, Sony HVR-A1U HDV video camera and Amphibico housing, and a 3.5" LCD color external monitor. All components of the enhanced mosaicing system were mounted in an aluminum/stainless steel frame (Fig. 1). The enhanced acquisition hardware allows for simultaneous collection of video and photographic stills using two independent cameras mounted on the same frame.

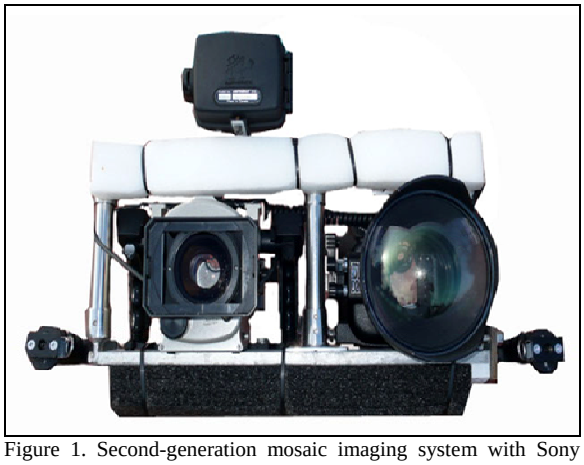

Figure 1. Second-generation mosaic imaging system with Sony HVR-A1U camera and underwater housing (left), Nikon 10 MP still and housing (right) and 3.5" LCD color video monitor (top).

In the field, the second-generation imaging system is deployed with both cameras in a down-looking position. Cameras are swum by a single diver 2 m above the reef area-of-interest in a double lawn-mower pattern as described previously (Lirman et al. 2007).

Data processing of the second-generation mosaic data is divided into two parts. First, a landscape mosaic is created using the same four steps as the previous generation of mosaic images with HDV images substituted for regular DV imagery (Lirman et al. 2007).

The second part of data processing represents a new step designed to register high resolution still images to the landscape mosaic. Automated feature matching algorithms (Lowe 2004; Brown and Lowe 2003) are used to map the still images to their geographic locations within the video mosaic. This mapping is obtained by matching individual still images to individual video frames used to create the landscape mosaic of the survey area.

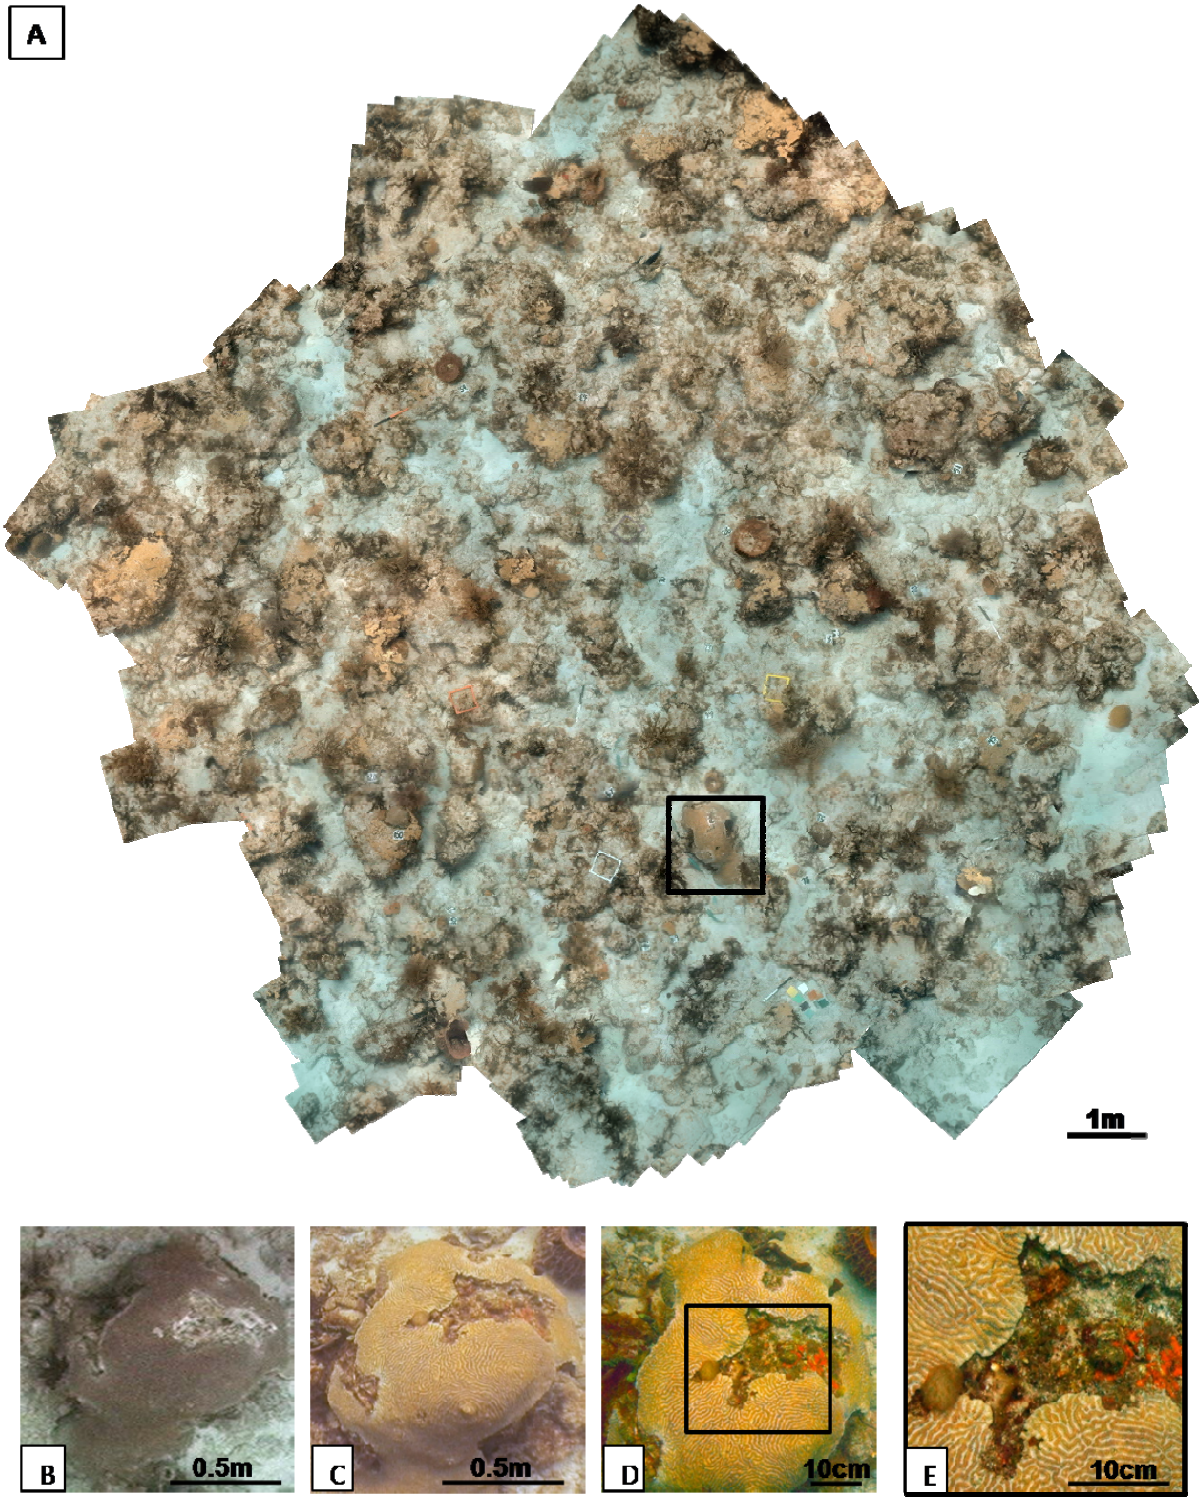

Figure 2. (A) A second-generation video mosaic from Brooke's Reef, FL taken in June 2008. Images of a *Meandrina meandrites* colony (shown in A) selected from mosaic surveys created using: (B) a Sony DV camcorder in June 2004, (C) high definition Sony camcorder from June 2008, and (D-E) 10 MP Nikon D200 still camera. All images were acquired at a distance of 2 m from the benthos. The combination of high resolution still images with video acquisition provides increased reef health information such as (D) tissue partial mortality and (E) cyanobacterial, macroalgal, and sponge interactions.

As a result of this process, each video frame used in the mosaic creation process is linked to a corresponding still image.

Display software was developed that allows users to select any point within the landscape mosaic produced by the second-generation imaging technology and retrieve the corresponding 10 MP still image and corresponding video frame of the area surrounding that point.

Results

In June 2008, a portion of Brooke's Reef, FL (25° 40.508'N, 80° 5.908'W) was mapped with the second-generation system. The landscape mosaic generated from the high-definition video of the second-generation system covered 156 m^2 (Fig. 2A). The first-generation landscape mosaic of Brooke's Reef taken in June 2004 has a spatial resolution of 3 mm/pixel (Fig. 2B), whereas the second generation version has a spatial resolution of 2 mm/pixel (Fig. 2C). The second-generation still camera images were acquired at a frame rate of 1 fps, resulting in approximately 1,800 10 MP images of the reef benthos. The 1,800 still images were then matched to key video frames. The average spatial resolution of the still images from the second-generation system was 0.4 mm/pixel, almost an order of magnitude improvement over the video of the first generation system (Fig. 2D, E).

The 2 mm/pixel spatial resolution of the second-generation landscape mosaic, produced from the high-definition video, enabled improved analysis of the mosaic. Boundaries between sponges, corals and gorgonians were clearer and large colony identification (> 25 cm) was possible for most Caribbean species (Fig. 2C).

Analysis of the 10 MP still images from the second-generation system provided the greatest taxonomic resolution. The sub-millimeter resolution of the still images allowed for species-level identification of colonies as small as 3 cm in diameter. In addition macroalgal groups were identifiable to genus with species level identification possible for macroalgae with obvious defining characteristics such as *Halimeda tuna* and *H. opuntia*. Coral colony health information such as partial mortality boundaries and evidence of bleaching and disease were all recognizable using the still images. Small-scale indicators of reef health such as cyanobacteria, macroalgal, and sponge competition were also visible using high-resolution still data (Fig 2D, E).

Discussion

The first-generation video mosaics demonstrated that mosaic-based monitoring could be accomplished without trained, expert scientific divers, long dive times, or extensive tagging of coral colonies. This technique also allowed users to assess basic reef health indices and monitor coral colonies using a large-scale image-based approach that limited the need for extensive dive-time and provided long lasting visual information on the state-of the reef at the time of the survey (Lirman et al. 2007).

Second-generation mosaics retain these monitoring strengths while providing increased benthic resolution over the entire survey area, enabling species level information for most coral colonies. This allows greater taxonomic information with respect to percent cover and diversity indices than was available from first-generation mosaics. In addition, change detection

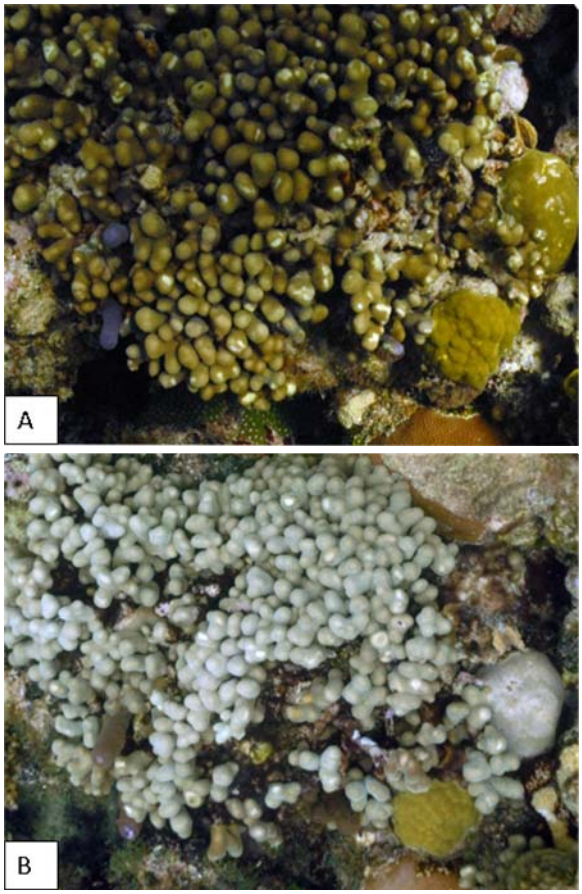

Figure 3. Example of change detection potential using second-generation imagery. High resolution still images were acquired from approximately 2 m water depth during video mosaic surveys. Images were automatically matched to their geographic locations within the survey area for change detection analyses. Between February, 2008 (A) and September, 2008 (B) the *Porites porites* (center) and *Stephanocoenia intersepta* (right) colonies shown above have undergone considerable paling. Evidence of partial mortality and an increase of cyanobacteria within the *P. porites* colony are also identifiable by comparing the survey images. Small indicators of coral health such as fish bite predation are also clearly present on both the *P. porites* and the *S. intersepta* in February 2008 and can be followed through time to monitor long-term impacts (A).

analysis using second-generation mosaic products provides information on conspicuous indices of reef health (such as bleaching and tissue loss) while also allowing users to monitor fine scale stressors such as macroalgal and cyanobacterial interactions and predation events (Fig. 3). This represents a significant monitoring improvement over first-generation products that could only discern dramatic indicators of colony health such as bleaching, and significant tissue loss (Gleason et al. 2007).

Although many monitoring programs take pictures of the reef for analysis and documentation purposes, the extensive cataloging and database management required in the laboratory often limits the amount of photographic data acquired during a survey. The automated matching of high resolution still images to their geographic location within a second-generation mosaic removes the need for user-intensive laboratory cataloging and allows the archiving of several thousand high resolution images of a reef area with minimal user input.

Image-based techniques for reef monitoring have an excellent archive potential that is vastly superior to written notes by divers. The second-generation mosaic survey technology described here provides both landscape level and colony level (as small as 3 cm) permanent records of the state-of-the-reef at the time of the survey without increasing the dive-time of first-generation mosaic products. The simultaneous capture of both of these scales of information allows users to monitor large-scale changes in reef communities such as hurricane or ship grounding damage, as well as small scale interactions such as sponge and macroalgal competition using the same survey design and the same raw data set.

Conclusions

The incorporation of high-resolution still imagery into the second-generation imaging equipment and mosaic processing resolved the species identification limitations of the first-generation system.

The ability to capture high resolution images over 100's of square meters and georeference these images within video mosaics without user input is a major advantage of the landscape mosaic technology. The combination of large-scale image maps and high-resolution benthic information provides a unique tool that maintains the strengths of most traditional monitoring methods, such as the ability to extract indices of reef health (percent cover, coral colony sizes, and diversity indices), while also providing a rapid method to document and assess changes at both large and small scales in coral communities without extensive tagging. This combined with the extensive archive potential inherent to this technology provides a significant advancement in coral reef community monitoring technology.

Abstract
Effective coral reef management requires early identifications of potential sources of contaminants before significant degradation of the reefs occur, allowing stakeholders, politicians, businesses and concerned citizens to have sufficient information with which to take appropriate, timely remedial action. The Rainbow Sensor program can provide a reliable, continuous, low-cost measurement of the organic content of seawater, needed by managers in economically important marine protected areas to monitor basic water quality information near significant human development. Increases in organic content can come from the addition of nutrients and hence algae growth or dissolved and particulate organic contaminants from land. The Rainbow Sensor uses spectral optical attenuation of light through the water column to detect the presence of shore based, human generated contamination. The first implementation of the moored Rainbow Sensor, the Light and Motion Sensor Program (LMSP) on Bonaire has, in its first year, shown that it can detect organic matter in the water column. The low cost (< US $1500) of each Rainbow Sensor mooring brings the capability of continuous, long-term measurement of the organic content of seawater to many agencies that do not have the budget for more expensive traditional monitoring systems.

Key Words: organic matter, contaminants, monitoring, light attenuation, water quality

Introduction

Coral reefs are vulnerable to a range of environmental effects, from the local to global scales. The local scale includes several types of effects. Removal of fish or shifts in population structure due to invasive species (top-down effects) can result in loss of grazing pressure on reef algae (Littler et al. 2006). Reefs can also be affected by mechanical damage. Mechanical damage can come from either human activities that include construction, boat anchors or diving activity or from natural processes such as wave damage during hurricanes. Bottom up effects come from modification of the base of the food web such as increased algal growth due to nutrient input, contaminants, or other processes that will affect the lower trophic levels (e.g., Lapointe 1997). Nutrient and contaminant inputs are usually associated with anthropogenic sources that increase with increasing population pressure that has resulted both from modernization and population migration to coastal regions. Regional processes often include fluctuations in regional circulation, eddies, coastal upwelling, storm systems, etc. Global processes include global climate change (IPCC 2001), ocean acidification (Caldeira et al. 2007; Feely et al. 2004), and global climatic oscillations. Climate variaibility has been suggested as a possible mechanism for rapidly altering the state of the ecosystem (Scheffer et al. 2008). Local processes, usually the most manageable processes, are often associated with human activities that include coastal modification, watershed and land use changes, sewage discharge, etc.

Maintaining as healthy a reef system as possible by local intervention may offset some of the effects of changing global and regional phenomena. Providing marine protected area managers with indications of increasing contamination levels that could degrade a reef enables them to seek effective solutions, ideally, before significant degradation occurs or becomes noticeable. Effective coral reef management, then, requires that contaminants are detected and identified before significant reef degradation can occur, so that the stakeholders can understand the presence and threat to a reef system and take preventive action as rapidly as possible.

The Light and Motion Sensor Program (LMSP) was developed to provide an inexpensive monitoring tool that will detect the presence and/or effects of contaminants in the water column. Anthropogenic inputs from runoff and sewage discharge into the coastal ocean (whether intentional or inadvertent) contribute inorganic nutrients contributing to algal growth, and organic matter that may alter the trophic structure of a reef (e.g., Lapointe 1997, 1999; Littler et al. 2006). Both organic matter and planktonic algae absorb light more strongly in the blue region of the spectrum than seawater (Kirk 1994; Fig. 1). Runoff and sewage discharges are characterized by increased colored dissolved organic matter (CDOM), suspended particulate matter and nutrient inputs (e.g., Petrenko et al. 1997; Twardowski and Donaghay 2001; Wu et al. 1994). Thus, it should be possible to create an index of the organic matter content of the water column, the organic index.

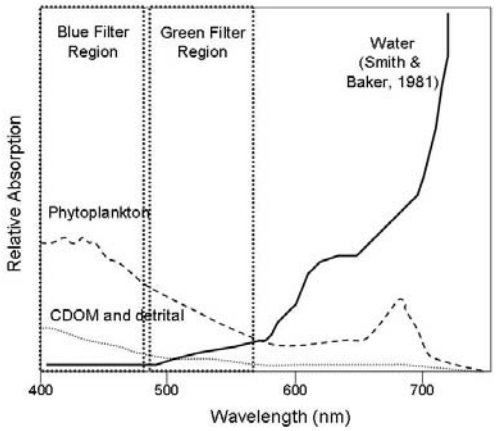

Figure 1: Sketch of Rainbow Sensor absorption spectrum. X-axis: light spectrum; Y-axis: Relative absorption of light in the water.

In clear oligotrophic water, attenuation in the green portion of the spectrum is typically higher than attenuation in the blue portion of the spectrum (Smith and Baker 1981). In the blue range, K_{Ed} increases due to increased absorption by organic matter while the green K_{Ed} is largely unaffected. Therefore, the Organic Index (OI) is correlated with: chlorophyll concentration (phytoplankton biomass), CDOM, and particulate organic matter.

This paper describes this approach and provides examples from the first year of implementation that indicate the utility of this monitoring system.

Material and Methods

The Light and Motion Sensor Program on Bonaire uses the Rainbow Sensor array developed at the University of Southern California to measure K_{Ed} for blue, green and broadband white light from sensors at three depths. The program uses Hobo Pendant temperature/light sensors (Onset Computer) with transparent colored filters inserted in two of the sensors. The three sensors are placed in an array at a specific depth below the surface (Fig. 2). On the LMSP moorings sensors are placed at 5 meter, 12 meter and 20 meter depths, for a total of nine sensors per mooring. The sensors are placed face up so that they are measuring the downwelling irradiance, E_d, at each depth for each spectral range.

Figure 2: LMSP Rainbow Sensor Array on a mooring line in the Bonaire National Marine Park.

The filters currently used by the LMSP program are blue and green filters with defined optical characteristics manufactured by Lee Filters, Inc. (http://leefilters.com). Figure 3 shows the transmission characteristics of the blue light filter. It transmits about 35-55% of the light between 400 and 450 nm. This portion of the spectrum is where CDOM and chlorophyll strongly absorb. The filter also effectively transmits light at 700 nm. However, water rapidly attenuates red light (> 600nm) in the upper few meters of the water column. At 700 nm, the seawater attenuation coefficient is 0.65 m^{-1} in the clearest seawater (Smith and Baker 1981), attenuating downwelling irradiance to 4% of its surface value at 5 meters depth. While there may be slight contamination of the blue light with red light using this filter at 5m, by 12 meters depth the downwelling irradiance at 700nm is reduced to ~0.04% of surface light.

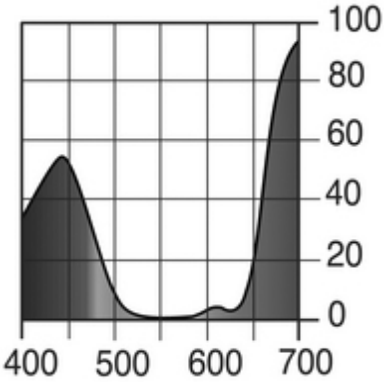

Figure 3: Blue filter transmission spectrum. The x-axis is the wavelength in nanometers and the y-axis is percent transmission. The spectrum is for the Lee Filter #798, Chrysalis Pink filter (http://www.leefilters.com/).

Figure 4 shows the green filter spectrum. The filter permits very little light in the blue range (< 470nm) but allows the entire green range (470-570nm) to pass. In this range organic matter affects light attenuation much less than at shorter wavelengths.

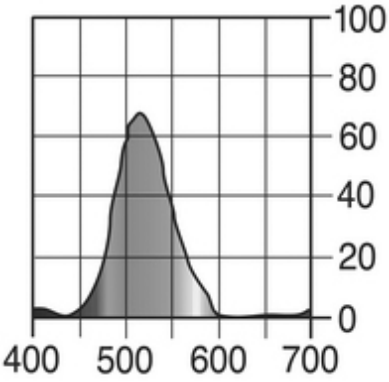

Figure 4: Filter transmission spectrum for Lee Filter #124, Dark Green (http://www.leefilters.com/). The x-axis and y-axis are the same as in Figure 3.

The sensors are programmed to measure temperature and light continuously at one minute intervals. Volunteer divers use an underwater optical reader to download data and re-launch the sensors on each mooring weekly. This data is transmitted to the University of Southern California in Los Angeles, California. Since the sensors are not self cleaning, the volunteers clean the sensors after downloading the data.

For each depth pair the diffuse downwelling attenuation coefficient [$K_{Ed}(\lambda)$] is calculated from the downwelling irradiance for each color region using equation 1.

$$K_{Ed}(\lambda) = -\frac{\ln\left(E_d(\lambda, z_2) \big/ E_d(\lambda, z_1)\right)}{z_2 - z_1} \quad (1)$$

where:

$Ed(\lambda,z)$ = downwelling (downward propagating) irradiance at wavelength λ at depth z

$K_{Ed}(\lambda)$ = diffuse downwelling light attenuation coefficient.

For each mooring nine K_{Ed}'s are calculated, blue, green and white sensor pairs for the depth intervals of 5-12m, 12-20m, and 5-20m.

The LMSP on Bonaire currently (September 2008) employs twelve moorings, each with nine sensors, distributed along the western leeward coast (Fig. 5). Two more moorings are expected before November 2008.

Figure 5: Locations of LMSP moorings on Bonaire along the central leeward coast.

Results

The Light and Motion Sensor Program on Bonaire has, in its first year, yielded results that show several processes that affect both the temperature and water quality on the reef. One of the moorings was located at a dive site called "Front Porch", indicated by #1 in Figure 5. During January 2008, the water column cooled by nearly 1.5°C accompanied by a doubling of the optical index (OI), calculated as the difference between K_{Ed} (blue) and K_{Ed} (green) (Fig. 6).

The temperature cooling suggested that this was likely an oceanographic process that was causing the change in the optical attenuation. MODIS-Aqua remotely sensed sea surface temperature (SST) and chlorophyll imagery (University of South Florida, Center for Remote Sensing) showed cool, chlorophyll-containing surface water extending northward from the Venezuelan coast, apparently due to coastal upwelling. Thus the cooling and increasing

OI on Bonaire advected from the Venezuelan coast to Bonaire, increasing the organic index resulted due to increased chlorophyll associated with the upwelled water.

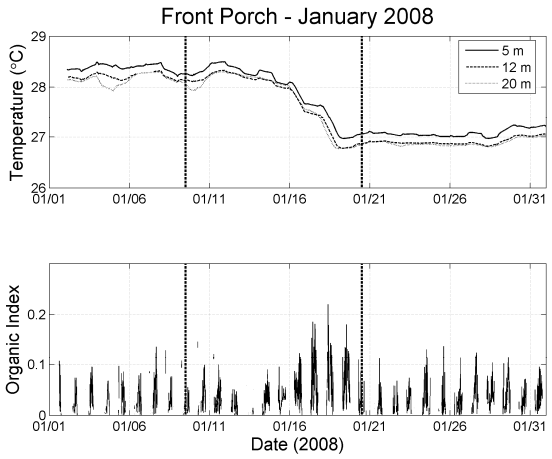

Figure 6: Time-series of temperature (top graph) and organic index (bottom graph) ($K_{\mathbf{Ed}}$ (blue, 12-20) –$K_{\mathbf{Ed}}$ (green,12-20)) for Site #1 (see Figure 2) in January 2008.

In the second example from the LMSP data set the seasonal variation from October 2007 through June 2008 is examined. During this period, K_{Ed}(blue) was often less than K_{Ed}(green), giving a negative organic index.. We therefore show only K_{Ed}(blue), which by itself is as an index of organic matter because of the strong blue absorption by phytoplankton and dissolved organic matter in the blue portion of the spectrum (Fig. 1). The time series showed a general increase in the K_{Ed}(blue) along the entire developed coast of Bonaire between November 2007 and April 2008 (Fig. 7).

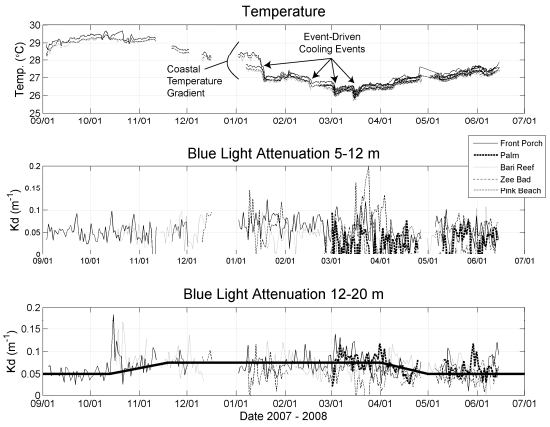

Figure 7: Example of possible local processes along the Bonaire coast. This includes data from 5 moorings.

This period coincides with seasonal cooling and is also concurrent with the highest tourist activity. The general pattern is consistent across several sites, suggesting that the increase in K_{Ed}(blue) is not due to localized contamination at any single site, and may likely result from increased mixing and primary productivity during the winter months. The K_{Ed}(blue) values in this time series are consistent with observations off the northwest coast of South America away from the influence of the Amazon River plume (Del Vecchio and Subramaniam 2004).

The observed seasonal cooling is not a continuous process, but is characterized by several step-wise cooling events of varying magnitude. The temperature data has been particularly useful in understanding the local and regional mechanisms that affect the reef.

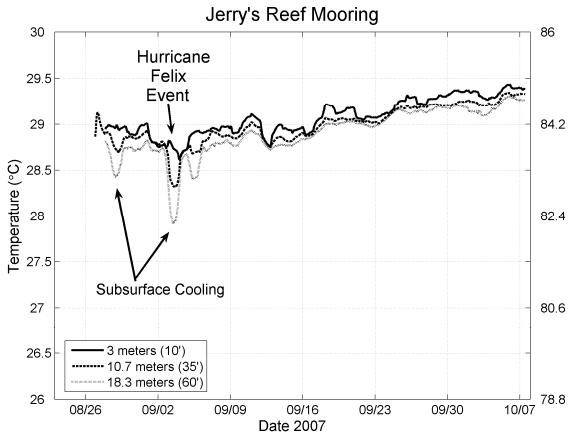

Figure 8: Vertical temperature structure during a near pass by hurricane Felix on September 2, 2007. The mooring site is Jerry's Reef near island of Klein Bonaire.

Figure 8 shows the effects of the passage of a hurricane event on the subsurface temperature. The temperature time series indicates that the cooling occurred from below rather than mixing downward from the surface. Cooling at 20 m preceded slightly the cooling at shallower depths. This contrasts with the cooling shown in Figure 7 where temperatures at all depths converged and the cooling event in Figure 6 where temperatures fell proportionally. By September 9, the effects of the event had passed and seasonal warming continued.

Discussion

After its first year of implementation, the Rainbow Sensor array has demonstrated that it can detect events in both temperature and in the diffuse attenuation coefficient in the blue portion of the spectrum. Two patterns in blue absorption were observed. One was a response to regional coastal upwelling off of Venezuela that could be seen in the remote sensing imagery to advect cool, chlorophyll enriched water toward Bonaire. The second pattern was a seasonal pattern where higher values of

K_{Ed}(blue) were observed during winter months than during spring/early summer. We are uncertain of the cause of the winter increase of attenuation, but nevertheless, the moorings were able to detect the pattern.

Improvements to the Rainbow Sensor array continue. The filter that is being used for the blue measurements also transmits light in the red region of the spectrum (Fig. 4). Although the downwelling irradiance at 700 nm is reduced to 4% of surface light at 5 meters, it may still cause a small amount of contamination in the total light and bias the K_{Ed}(blue) values higher because of the high values of red attenuation by water itself. We are looking for a suitable filter that has adequate transmission in the blue portion of the spectrum and minimal transmission in the green and red parts of the visible spectrum.

The low cost of the moorings (< US $1500) provides the possibility of continuous, long-tern measurement of the organic content of seawater to agencies that do not have the budget for more expensive traditional instrument systems. Manufacturers such as WETLabs and Satlantic produce *in situ* nutrient sensors that cost US $15-20,000 each. Similarly, CDOM and chlorophyll fluorometers cost about US $3500 each and require additional battery packs and loggers for moored applications. Although these more expensive instruments provide specific, accurate measurements, the costs of implementing a mooring with these sensors may rapidly become prohibitive.

This approach is applicable to coastal reef systems near human development where the effect of human generated pollutants could affect the health and economic viability of the reef. The approach is best suited for coral reefs at greater than 5-10 meters depth and where volunteers and/or low cost individuals that are only recreational SCUBA qualified are available and allowed to service the sensors.

We are continuously improving the procedure for the Rainbow Sensor and for analysis of the time series of temperature and K_{Ed}. We welcome the opportunity to collaborate with other groups interested in implementing this approach.

We conclude that the "Rainbow Sensor" concept appears to provide a reasonable measure of K_{Ed} in the blue portion of the spectrum. Because most of the variability between 400 and 490 nm is associated with organic matter in various forms including CDOM, chlorophyll and particulate organic material, variability of K_{ed} in this region of the spectrum should represent changes in the organic content of the water column. We believe that the Rainbow Sensor array is an effective, inexpensive approach to monitoring changes from contamination that might affect the reef ecosystem. Because it records its data at a reasonably high frequency, it provides the ability to resolve processes over a range of time scales range from minutes to years, depending on the lifetime of the moorings.

Acknowledgements

We thank the LMSP volunteers who have faithfully and expertly installed, and serviced the LMSP sensors. Bonaire National Marine Park has provided support and assistance for this program. Finally, we are grateful to Ms. Blue McRight and all the donors who selflessly provide funds for this program and the SeaMonitor Foundation for providing continuing support. Development of the concept was supported by NASA Ocean Biology and Biogeochemistry.

Abstract. In the profit-oriented business and industry sector, information management (IM) solutions are well established. But in coral reef ecology, the IM aspects of experimental design, data acquisition and evaluation, documentation and publication follow the individual workers' experience rather than established standards. Although these tasks are largely automatable, no useable guidance tool has been established so far that would lead the worker through the experimental life cycle and enforce validation, documentation, completeness, correctness and consistency of data. Often, this causes loss of information and diminishes data quality as well as compatibility. We developed COREweb, a dynamic web application to automate the scientific work process in consistency with established scientific work practices. The underlying data model is capable of managing any kind of manipulative or monitoring ecological experiment. The user operates COREweb through an intuitive Graphical User Interface and focuses on the scientific experimentation and validation process. Data can be shared among team members. COREweb is scalable from a single-user, single-desktop environment up to a distributed network, connecting teams worldwide. As COREweb is easily adapted to many different scientific experiments, it can serve as a prototype model for useable scientific IM tools that make valuable data better available to decision makers.

Keywords: Scientific work flow, process model, data model, information management

Introduction

In life sciences, researchers proximately want to publish as fast and high-ranked as possible with the least effort of time, financial and personal resources. Therefore, any means of facilitating and improving the scientific work flow should be in their best interest. Information management (IM) is the collection and management, *i.e.* the organisation and control of the structure, processing and delivery of information. Information in research projects consists of the experimental data itself, the metadata, instructions on methodology, best practices, abided protocols and standards as well as any uncategorized information which ultimately helps a research team to gain knowledge. A rising number of collaborators, close and remote, requires means of online collaboration and tools to share data and knowledge. The following tools and standards exist for this purpose.

Metadata and data standards The ecological markup language (EML) is an extensible markup language (XML) extension that serves to document and handle ecological metadata (http://knb.ecoinformatics.org/software/eml/). Metadata are needed for the identification and documentation of the multitude of heterogeneous ecological and environmental data sets. However, proper documentation via metadata depends on the individual worker's motivation and is therefore not very prevalent.

In some software packages, such as ECOBAS (Benz et al. 2001), data completeness, correctness and consistency is automatically enforced by the package's functionality.

Experimental design and data modelling Calvin Dytham presented a simple-to-use decision tree to guide the scientist from the formulation of their research questions towards the choice of an appropriate statistical test (Dytham 2003).

The software *Touchstone* allows the user to refine the experimental design in a "what if" style until a statistically satisfying setup has been found (Mackay et al. 2007).

Pratt (1995) designed a relational database schema which can store the data of empirical studies. The schema bases on a model of an empirical study of natural processes.

Work flows and method provenance Kepler automates work flows, i.e. the processing steps from raw to analyzed data (Bowers et al. 2006), and features a model for user-oriented data provenance in pipelined scientific workflows. Provenance information may also be used by scientists to reproduce results from earlier runs, to explain unexpected results, and to prepare results for publication. Bowers et al. (2006) developed a simple provenance model that is capable of supporting a wide range of applications even for complex models of computation, such as process networks.

The *Karma* provenance framework provides a means to collect workflow, process, and data provenance from data-driven scientific workflows (Simmhan et al. 2006) in order to retain the knowledge that was put into the experimental planning and refinement.

Data lineage Bose and Frew (2005) review the data quality benefits of lineage, i.e. the documentation of data origin and processing history. Lineage helps to understand data processing steps (Woodruff et al. 1997), enhances interpretation, prevents misinterpretation of data and communicates data suitability, reliability, accuracy, currency and redundancy (Eagan et al. 1993). Lineage also facilitates the use of historical data (Clarke and Clark 1995).

Process models In software design, several procedures exist which structure and guide the process of coding new programs. The V-model (Boehm 1979) is one approach that parallels ecological experiments.

In the V-model, the initial steps of conceptual planning preceding the actual writing of source code are designed with regard to the requirements of the later steps of testing and evaluating the software. The writing of source code begins only once its desired functionality is defined and understood.

Since the V-model's "think-first" approach helps eliminating ambiguity and identifying non-trivial requirements, the time spent with planning ahead pays off at the stage of generating the source code.

Similarly, the researcher has to design manipulation and observation routines with regard to the statistical power of the generated data in order to avoid generating data with a low statistical power and, therefore, losing valuable time and financial resources.

Aim of this study This study aims to incorporate these established standards and best practices into a process model of an ecological experiment by abstracting the ecological work process and its related artefacts into formal languages. This is achieved through the graphical user interface (GUI) structure and database schema of a database-driven web application, which provides modular tools that guide and assist the user through the experiment's life cycle.

Materials and Methods

Via model-driven development (MDD), COREweb was generated to a large extent from the formal language artefacts using Grails, a MDD framework (Rocher et al. 2006). COREweb is a model-view-controller (MVC) web application, which provides a separation of the database structure (model), the GUI (view) and the functionality (controller).

The COREweb prototype currently supports the process up to the generation of the data structure. It is possible to setup and thoroughly document the experiment, enter the raw data with input validation at a user-defined level and export the validated, well documented data and metadata for processing and statistical analysis.

COREweb is deployed as a Java applet, connected to a postgres database, runs on a web server and can be accessed in any browser via the inter- or intranet. The database and the java applet can run on one or on different machines. Source code, technical documentation and a walkthrough using an example experiment are available at http://palmuc.de/core/coreweb/ .

Results

Abstracting the experiment into a database schema

Methods consist of several manipulative or observational steps. Samples are the individual experimental units, which are manipulated and observed. Observation results in the measurement of their properties.

A sample experiment is shown in Fig. 1; two methodical steps result in a total of five different measurements. The sum of measurements and the number of samples define the data structure, paralleling the columns (measurements) and rows (samples) of a spreadsheet.

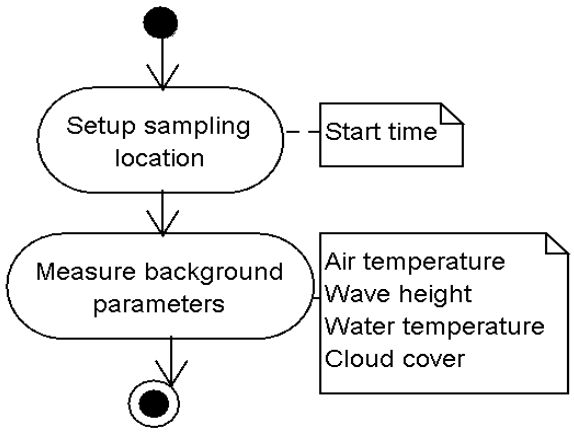

Figure 1: A sample experiment with two methodical steps (round boxes) and five measured parameters (rectangular boxes).

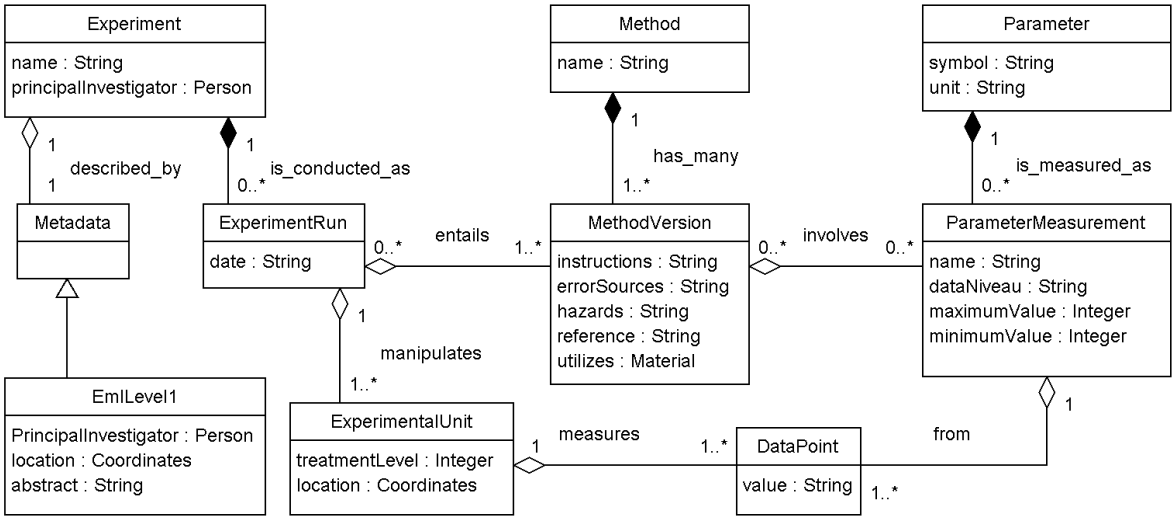

Figure 2: Simplified data model of an abstracted scientific experiment, shown as a UML class diagram. Each class, represented by a box, corresponds to a data table in the database backend. Each relation between classes, represented by a connecting line, corresponds to a foreign key in the database backend.

A database schema was designed that can store information on metadata, documentation, methodology, information on experiments, their individual realizations (runs), the samples and the measured parameters by only adding entries to the existing tables (Fig. 2).

In contrast to conventional spreadsheets, the data points are linked to their methodical origins (MethodVersion) and metadata documentation, providing data lineage, method provenance and semantics via metadata.

The database backend itself is hidden from the user, who interacts with the application through an intuitive GUI front end (Fig. 3), which unobtrusively offers best-practice functionalities at the appropriate process stages of the experiment and implements standards, e.g. the EML metadata format. MDD allowed a large portion of code to be generated from the database schema.

Process model of an ecological experiment Paralleling the V-model, a proposed work flow of an ecological experiment, based on manipulation and observation, was modelled in the unified modelling language (UML, information and tutorials at **http://www.uml.org/** , Fig. 4). It features iterative testing using automatically generated dummy data, automation of the data processing and evaluation steps and refinement of the experimental design. It focuses on the statistical power of the generated data.

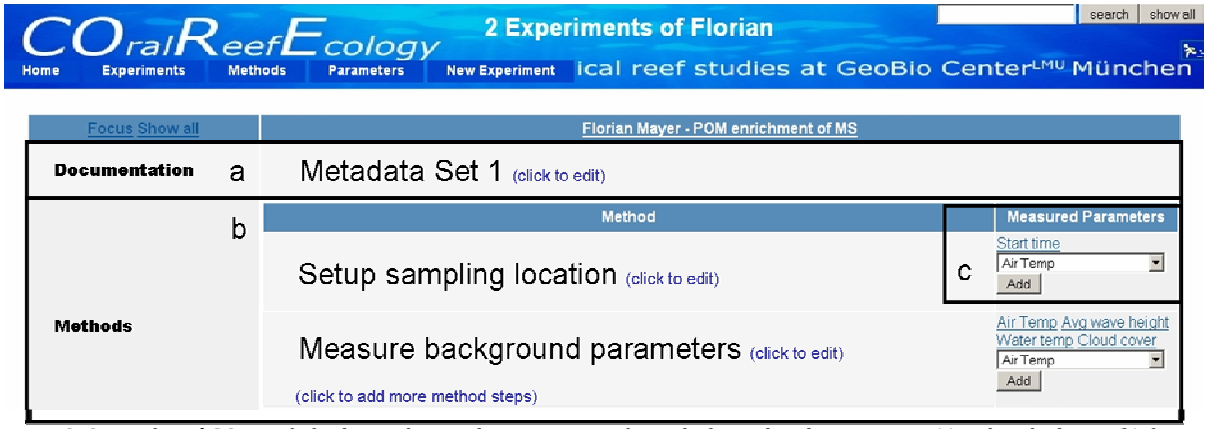

Figure 3: Screenshot of COREweb displaying the sample experiment with attached metadata documentation (a) and method steps (b) during which several parameters (c) are measured.

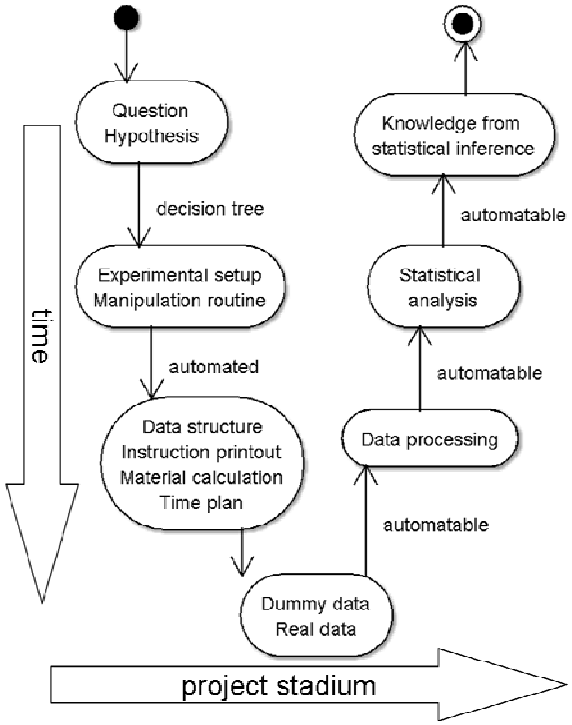

Figure 4: Process model of an experiment. The process can be dry-run and refined using dummy data. Real data should be generated after the "dry-run" validation of the process.

The proposed work flow consists of:

(1) The initial description of the planned experiment and formulation of the questions and hypotheses. Input masks channel this information into valid EML metadata; reporting functions produce an initial project outline from the entered information.

(2) Choosing the appropriate statistics to test the hypotheses following a decision tree adapted from Dytham (2003), leading to a possible refinement of the hypothesis and, ultimately, to the statistical constraints on the experimental setup.

(3) Choosing and documenting the experimental setup, the manipulation and sampling methods. Export functions provide methodical instructions, material requirement lists, a Gantt-chart style time plan, the sampling scheme, lineage documentation and the resulting data structure in form of a data table. Figure 5 shows the data table resulting from the sample experiment shown in Fig. 1. At this stage, the user can map the statistical constraints (e.g., one grouping variable, one affector and one responder variable *sensu* Pratt (1995)) onto the respective parameters.

(4) Validation of the planned experiment using automatically generated dummy data in form of a separate "experimental run." Implementation of an export into comma separated value (CSV) spreadsheets is pending.

(5) Transformation of raw dummy or real data into processed, analyzable data. This step is potentially automatable via workflows (e.g. using *Kepler*). Bulk import of existing data, such as sensor data, will be implemented in this step.

(6) Statistical analysis of the data for inference and evaluation of the hypotheses. Pipelining the data and desired statistics as input arguments; the analysis in the software package R can be automated as well as the export to CSV spreadsheets. As the least common denominator file format, CSV can be read by most analysis packages.

(7) Interpretation of the statistical output and transformation of the analysis into knowledge.

Up to this stage, dry-testing the process with dummy data entails continued documentation and refinement of the experiment. As soon as the experiment is validated and the statistical power of the experimental setup is satisfactory, the process steps 1 - 7 can be used to conduct the real experiment. The EML metadata will be made exportable to a readable table format using style sheets as well as to established metadata databases.

Service-oriented architecture (SOA) The single work steps are implemented as optional services, so the user can choose between guidance and self-determination. COREweb functions as a framework with plug-ins of existing technology; the least common denominator data structure (see Fig. 2) makes data and information compatible between the modules.

Discussion

Advantages of software-conveyed guidance The database schema of COREweb is able to store raw data from ecological experiments. In combination with appropriate metadata documentation, results compatibility and transparency of data sets.

Data completeness, correctness and consistency can be easily enhanced by the GUI's input validation. For example, by simply filling in the metadata form fields, the user creates valid EML metadata without having to know EML. Similarly, the user can determine the data type of the measured parameters. From these constraints, the software can validate input, e.g. warn if characters are entered in a date field.

Automation and simulation via dummy data encourages the user to simulate the experiment in advance and to subsequently refine the planned process. This may save time and financial resources, if e.g. the number of samples can be optimized.

Early documentation creates a quick overview of the planned methodology. Incremental refinement of both the documentation and the methodology provenance *sensu* Bose and Frew (2005) provide advantages for the team in terms of consistent methodology and knowledge exchange. It also leads to raised data compatibility and quality.

Assigning the statistical relevant terms (e.g., grouping variable, affector, responder) onto the data structure helps to document the experiment's semantics.

Following a user interface's work flow implicitly and unobtrusively guides the user along the implemented standards and best practices.

Challenges for a computerized IM solution Mueller (1994) after early studies with computerized heuristic tools for engineers found that "it is not in the human nature to work rationally dominated". Until now, no IM solution successfully integrates standards and best practices into the scientific work process. This may indicate that on the one hand, known benefits of adhering to those standards and best practices do not feed back quickly or tangible enough into a speed-up or improvement of the user's own work process. On the other hand, Jagadish et al. (2007) emphasized the lack of usability of recent IM software. For non-scientific use however, intuitive and very well useable web applications exist, such as social networking platforms, which collect user-generated data and provide connectivity by addressing the users' play instinct and acquisitiveness. COREweb tries to overcome the user's initial reluctance with tangible rewards, e.g. documentation spin-offs like material calculation lists, time plans and field instructions that can be set up quickly and refined subsequently as well as with a good usability.

Mueller (1994) also found that his test subjects did not use software solutions voluntarily. Our SOA approach leaves most guiding functionalities optional; therefore, the user retains maximum autonomy.

Although the GUI of COREweb was purposefully kept simple in order to focus on development of the key functionalities, the ongoing implementation as an MVC web applet allows a refinement of the GUI towards a smooth and increasingly intuitive interface.

Summary

The software prototype COREweb implements core functionalities of the scientific work flow, implicitly integrating established standards and best practices.

Via automation of the data processing and analysis steps, COREweb facilitates a test-first approach using dummy data. Documentation rewards the user through the feedback loop of useful printout artefacts, such as material calculation lists, time plans or work instruction sheets.

Further development of COREweb will increase usability and smoothness of the work flow as well as it will implement more functionality.

2) Woods Hole Oceanographic Institution, Woods Hole, MA 02543

Abstract. Although remote sensing technology is a useful tool for monitoring shallow (<20 m depth) coral reefs present in clear oligothrophic waters, the large-scale assessment of reefs present in optically-deep waters requires other approaches such as the use of *in situ* platforms for high-resolution optical and acoustic imaging. Optically-deep waters are those where the upwelling radiance received by the airborne or satellite sensor originates from the water column without any bottom signal contribution. The Seabed autonomous underwater vehicle (AUV) is an ideal platform for mapping and characterizing mesophotic reefs, those present between 30 to about 100 m depth, and for shallow reefs in turbid areas. This AUV was utilized to acquire high-resolution digital images to characterize the geomorphology and dominant benthic components present along two long photo-transects in southwestern Puerto Rico. These quantitative AUV surveys also provide a baseline for future evaluation of change in the deeper coral reef zones, which for most areas of the world, remain largely unknown.

Key words: Mesophotic reefs, Seabed AUV, Puerto Rico, optically-deep waters

Introduction

Coral reefs, one of the most productive and diverse of all ecosystems, are increasingly at risk due to anthropogenic effects and global climate change. Although the use of remote sensing from aircrafts and satellites has been successfully used for mapping and monitoring coral reefs, there are many limitations in the use of this technology. For instance, the spectral and spatial resolution of existing sensors, the confounding effects of variable water optical properties and bathymetry are significant obstacles for the implementation of this technology.

Other approaches such as *in situ* platforms and sensors are required for benthic habitat mapping in turbid or optically-deep waters (i.e. where the signal received by the airborne or satellite sensor originates from the water column without any bottom signal contribution). This is also the case for mesophotic coral reefs (30-100 m) present in clear but deep waters, where the exponential attenuation by the water column precludes the use of optical remote sensing. For quantitative assessments of these deeper reefs we have used the Seabed autonomous underwater vehicle (AUV), which was designed for high-resolution optical and acoustic imaging. As a leading instrument in this field, the Seabed AUV has been successfully deployed for characterizing deep coral reef zones in the US Virgin Islands (USVI) and Puerto Rico (Armstrong et al. 2002; Singh et al. 2004; Armstrong et al. 2006; Armstrong 2007). The digital photo transects obtained by the Seabed AUV in these studies provided quantitative data on living coral, sponge, gorgonian, and macroalgal cover as well as coral species richness and diversity. Previously undescribed, well-developed coral reefs with 43% mean living coral cover were found at depths of 40-47 m south of St. Thomas, USVI (Armstrong et al. 2006).

Five digital phototransects of the upper insular slope at La Parguera and Guánica, southwestern Puerto Rico, were obtained in 2004 by the Seabed AUV. Results from the first two AUV transects that have been analyzed are presented here as examples of the capabilities and limitations of this technology.

Methods

The Seabed AUV is a stable platform that can be configured with a wide range of sensors including digital cameras and multi-beam sonars (Fig. 1). The AUV primary mission is to characterize seafloor benthic habitat by providing high resolution, color imagery in areas of steep and rugged terrain in combination with bathymetric and other oceanographic sensors. The Seabed is the only hover capable AUV that is able to conduct linear transects or detailed surveys of specific areas while maintaining a constant distance from the bottom. A Pixelfly 1024 x 1280 pixel resolution CCD camera, with 12 bits of dynamic range, is the primary optical imaging sensor. More information on Seabed components, sensors, control systems, and navigation can be found in Singh et al. (2004).

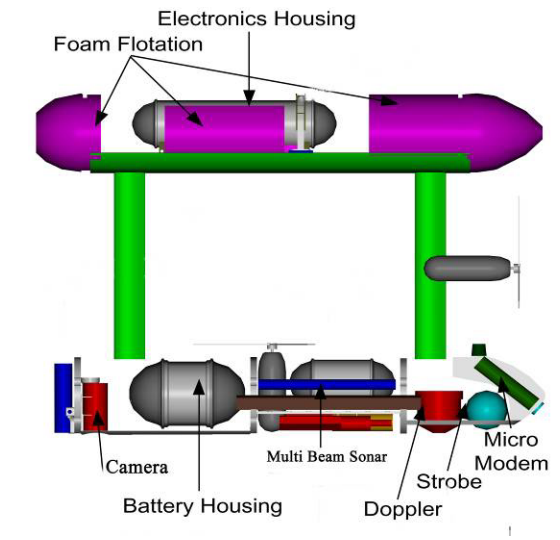

Figure 1. The Seabed AUV. Schematic diagram of the major components (top) and external view during deployment (bottom).

Seabed AUV high-resolution digital images, obtained in November 2004, were used to characterize the dominant components in two photo transects at La Parguera and Guánica, southwestern Puerto Rico. Each transect was approximately 400 m long and produced over 900 images, each measuring about 2.1 m wide by 2.0 m long. Every tenth image (n=90) along each transect were analyzed using 50 random points in the Coral Point Count with Excel extensions software (Kohler and Gill 2006). The dominant benthic categories were divided into: stony corals, gorgonians, sponges, algae/hardground, and unconsolidated sediments. The algae and hardground categories were combined since macro-algae and turf algae cover was extensive in hardground areas and the resolution of the images was inadequate for a more detailed analysis of these categories.

Results

Although the insular platform and shelf edge off La Parguera has the best developed reef system of the island, there is little information on the deeper reef zones in this area. The only published reports of the deep reef communities of La Parguera, to a depth of 125 m, revealed 25% coral cover at depths of 25-30 m but less than 2% coral cover at depths of 30-60 m (Armstrong et al. 2002; Singh et al. 2004).

The insular shelf in this area is 8-10 km wide with an average depth of 15-18 m from near shore to the shelf break (Morelock et al. 1977). The shelf edge has a buttressed-reef formation with channels that allow the movement of sand from the outer shelf to the upper insular slope, which descends at 43˚ in most places (Morelock et al. 1977). These authors report that there are no channels where the upper 30 to 40 m of the slope is vertical. The Parguera AUV transect started at 17°52.6' N, 60°2.6'W at a depth of 20 m and ended at depth of 94 m (Fig. 2).

The insular shelf south of Guánica Bay, located approximately 13 km to the east of La Parguera, is approximately 3-4 km wide and has average depth of 12 m. Extending southeast across the insular slope there is a submarine canyon that shoals to 12 m at the entrance to Guánica Bay (Morelock et al. 1994). The Guánica AUV transect started at 17°55.5' N, 66°52.3'W at a depth of 27 m and ended at a depth of approximately 130 meters (Fig. 3).

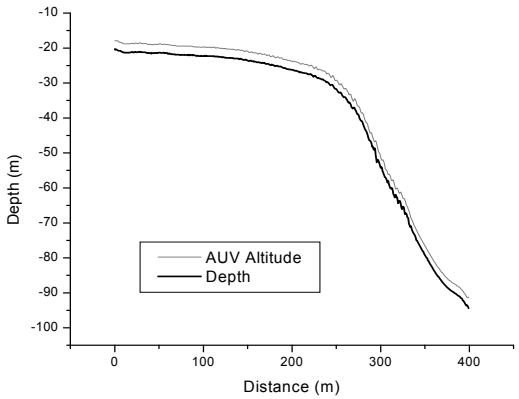

Figure 2. Depth profile and AUV altitude for La Parguera transect.

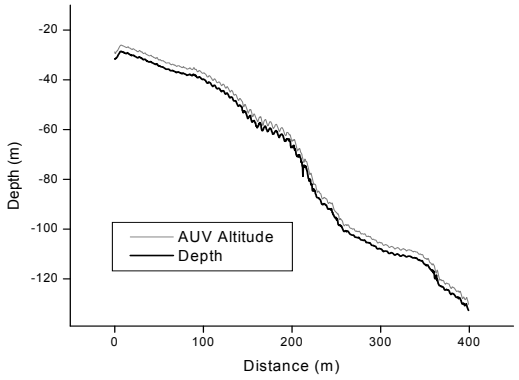

Figure 3. Depth profile and AUV altitude for the Guánica transect.

The La Parguera transect bathymetry reflects the geomorphology described by Morelock et al. (1977). The shelf-edge has a well-defined break from a gentle slope to one that is much steeper beyond the break, at a depth of approximately 30-40 meters (Fig. 2). The bathymetry at the Guánica transect (Fig. 3) is very different from the one observed in Parguera and can be described as a ramp. Ramps have no definite slope break and sediment facies grade evenly from sandier sediments associated with higher energy in shallower environments to muddier sediments in the low energy deeper water environment (Tucker et al. 1990). At both sites coral cover decreased with depth with the maximum percent cover of 7.8 and 4.0 for the Parguera and Guánica transects, respectively (Fig. 4). Notice that the 20-24 m depth interval was not present in Guánica and the 97-110 m depth zone was not sampled in La Parguera (Fig. 4, 6-9). The maximum coral cover in La Parguera was present at the shelf break, at a depth of 25-35 m and consisted of coral-sponge-gorgonian hardgrounds (Fig. 5a).

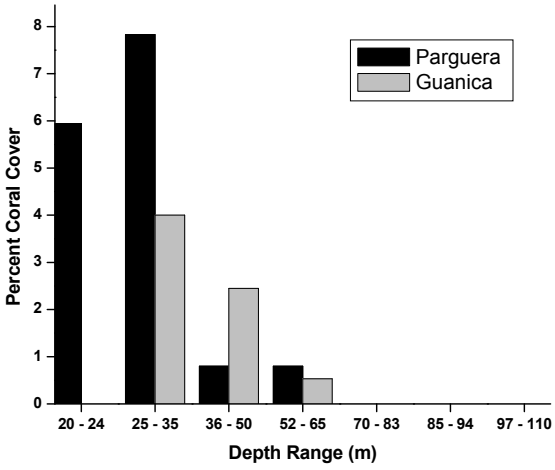

Figure 4. Percent coral cover by depth range for La Parguera and Guánica transects.

Similarly, the Guánica transect also lacked well-defined, structural coral reefs with hardgrounds also dominating the shallower geomorphology. Small isolated coral heads of the genus *Agaricia* were found to a depth of approximately 65 m in Guánica and to 87 m in La Parguera. Acevedo et al. (1989) reported that corals were present to a depth of 70 m in La Parguera.

The percent cover of gorgonians at all depths is more similar between the two transects with the highest values also present at the 25-35 m depth range (Fig. 6). After 65 m depth there is a noticeable decrease in gorgonian cover. Although sponge coverage was higher in La Parguera than in Guánica, dominance by sponges is apparent at both sites and

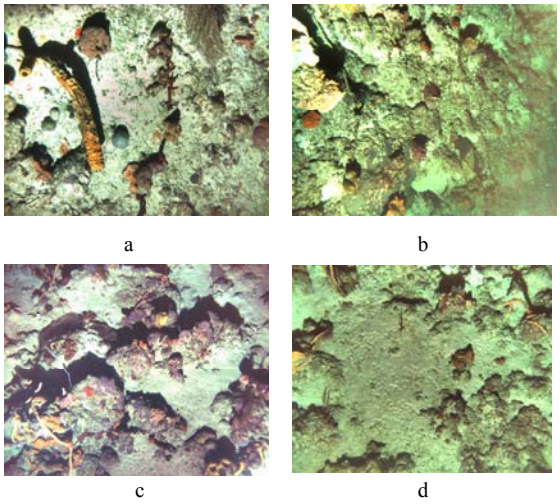

Figure 5. Hardground areas with isolated corals, sponges, and gorgonians dominated the two transects at the shallower to intermediate depths. AUV images from the La Parguera transect at 35 m (a), 67 m (b), 78 m (c), and 84 m (d) depths.

throughout all depths to 94 m (Fig. 7). Dominance by sponges, in the 30-100 m depth range, was also reported by Singh et al. (2004). Hardground areas with algae accounted for approximately 40% of the benthic cover in La Parguera and from about 40-70% in Guánica, both at depths less than 95-100 m (Fig. 8). The amount of unconsolidated sediment increased with depth, particularly at Guánica, where the highest amount of fine-grained sediments (96%) was found at the 97-110 m depth range (Fig. 9). A high degree of bioturbation at the deeper zones of both transects was evident from the AUV images (Fig. 5d).

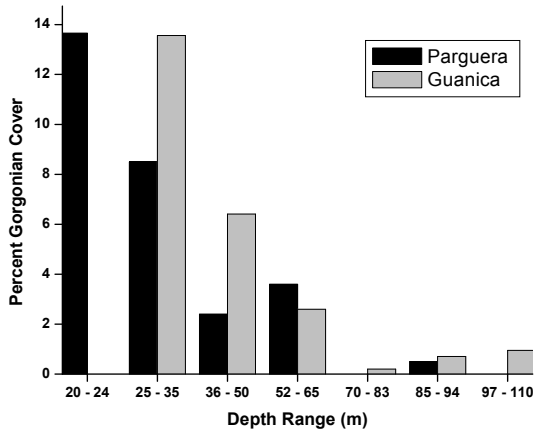

Figure 6. Percent gorgonian cover by depth range for La Parguera and Guánica transects.

Discussion

The high quality digital imagery provided by the Seabed AUV was used to describe and characterize the geomorphology and benthic habitats present to

depths of 110 m in southwestern Puerto Rico. These quantitative, geolocated AUV surveys also provide a baseline for future evaluation of change in the deeper coral reef zones.

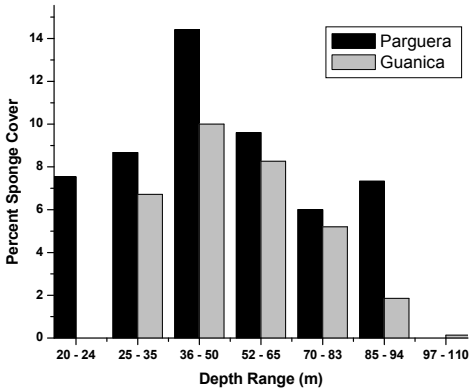

Figure 7. Percent sponge cover by depth range for both transects.

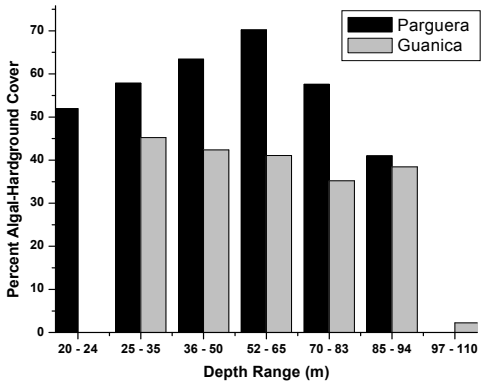

Figure 8. Percent algal-hardground cover by depth range for La Parguera and Guánica transects.

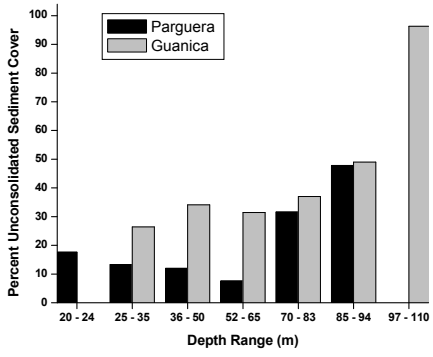

Figure 9. Percent unconsolidated sediment cover by depth range for La Parguera and Guánica transects.

Similar transects could also be used for large-scale mapping and monitoring of shallow (<20 m) reefs present in turbid insular shelf areas. In this case the AUV altitude from the substrate needs to be substantially reduced to minimize the light absorption of the water column allowing the capture of high contrast images. Besides benthic imaging, other sensors on the AUV such as fluorometers and turbidimeters can be used for monitoring changes in water quality parameters that are known to impact coral reef areas.

Reports on upper insular slope communities, from the shelf edge to 100 m depth, are scarce for the US Caribbean. Most of the research in this zone has been focused on fishery resources (Garcia-Sais 2005). The only published reports for Puerto Rico are from La Parguera, where coral cover was found to decrease from 24% at 25-30 m to less than 2% at 30-60 m (Armstrong et al. 2002; Singh et al. 2004). The results presented here from these two transects agree with the previous reports.

The depth limitations of conventional diving have left mesophotic reefs largely unexplored. Even though technical diving has extended the depth range of diving surveys, the large-scale assessments and monitoring of mesophotic reefs by divers remain impractical. The Seabed AUV has the distinct advantage of allowing frequent access to large areas of mesophotic reefs with an endurance of up to 8 hrs producing transects that could be several kilometers in length. In addition, data from Seabed AUV sensors and related imaging technologies can be used to conduct multi-beam sonar surveys, photo mosaicking, and multisensor fusion of acoustic and optical data.

Although the AUV uses a high resolution and dynamic range camera, the relatively high altitude of the vehicle from the bottom makes identification of certain algae, sponges, disease and other substrate types difficult. A comparison between the AUV and a diver-held video camera method showed similar percent cover values for scleractinian corals but increasing variation in other categories such as macroalgae, coralline algae, gorgonians, and sponges (Nemeth et al. 2009). The diver held video camera provided closer images which enhanced the ability to identify benthic organisms but greatly underestimated the percent cover of gorgonians (Nemeth et al. 2009). Also, detection of coral disease was most effective with direct visual assessment of individual coral colonies by divers.

The large-scale characterization and monitoring of coral reefs in optically-deep waters requires the use of *in situ* platforms equipped with optical and acoustic sensors. Optically-deep waters are present over large coastal areas of Puerto Rico where coral reefs are known to exist. Approximately 43% of the potential

reef habitat within the Puerto Rico-USVI insular shelf and slope is found between 30-100 m. The Seabed AUV has proven to be ideally suited for mapping and monitoring mesophotic reefs, which for most areas of the world remain largely unknown.

Acknowledgments

The Seabed AUV development and use was made possible by the Bernard M. Gordon Center for Subsurface Sensing and Imaging Systems (Gordon-CenSSIS), under the Engineering Research Centers Program of the National Science Foundation (Award Number EEC-9986821). We thank Belyneth Deliz López for data processing and the Caribbean Fishery Management Council.

GIS derived spatial analysis as a tool to predict nearshore coral reef fish species presence in American Samoa

D.P. Brown[1] and G.R. Allen[2]

1) National Park Service, Pago Plaza, Suite 114, Pago Pago, American Samoa 96799
2) Dept. of Aquatic Zoology, Western Australian Museum, Locked Bag 49, Welshpool DC, Perth 6986, Australia

Abstract. The U.S. National Park Service has undertaken a monumental task of inventorying species found within park boundaries. This is part of the Inventory & Monitoring program aimed to increase our management efforts in all the U.S. National Parks. In the National Park of American Samoa, the inventory of reef fish has helped to discover 47 new species records for the territory of American Samoa. This was done using both GIS polygons derived from known geographic distributions of marine fish as well as in-water surveys using SCUBA and technical diving procedures. Using ArcInfo GIS software, a distribution map was created for all known coral reef fish species from the central South Pacific. GIS benthic habitat maps were then used to locate suitable and likely locations for a given species. In-water surveys were then conducted to look for the predicted species. Using this technique 138 additional species were presumed to be located in American Samoa. To date the in-water surveys have found 47 new records, of these, 37 were assumed present from the GIS modeling but had never previously been found. Many of the remaining species are small and cryptic and are unlikely to be encountered without the use of ichthyocides.

Key words: GIS, predictive mapping, Samoa, coral reef, fish

Introduction

Though we often idealize the South Pacific as pristine and untouched, in reality many of the small tropical islands of the South Pacific have had significant alterations and anthropogenic influences. Increasing negative impacts on coral reef habitat and species abundance have been correlated with their proximity to greater population densities (Brainard et al 2008). As a result many governments, agencies, and private organizations have begun initiatives to identify, prioritize, and delineate areas of special importance so that we may mitigate anthropogenic influences (Pittman et al 2007, Allen 2008, Ward et al 1999).

In the United States one of the federal agencies that has begun this process is the U.S. National Park Service. It has undertaken the monumental task of inventorying and monitoring all species found within park boundaries both below water and on land. This is part of the Inventory & Monitoring program aimed at increasing management capabilities in all U.S. National Parks. As a part of this effort, a new fish species list for American Samoa was deemed necessary. Previous to this study the most recent list of fish presence data came from work completed 25 years ago. Researcher inventories, species lists, and museum collection records for Samoa were analyzed and it was noticed that they all emanated from similar, if not identical, collection locations and often from similar depth strata. It was then hypothesized that key habitats and various depth profiles may have been undersampled and overlooked during these previous efforts.

Predictive mapping for species presence and abundance is relatively well developed and routinely used in terrestrial environments (Pittman et al 2007, Miller et al 2004, Guisan and Zimmerman 2000). Within the marine environment much less predictive mapping has been done until very recently (Pittman et al 2007, Friedlander et al 2007, Spens et al 2007). Many of these studies are theoretically based, using computer models and statistical variables to ascertain species data and few have little if any "groundtruthing" of the predicted species presence. In this study, we make fish species presence lists based on predictive modeling using GIS based methodologies as well as in water observations. We sought to sample both historical collection sites as well as additional undersampled areas based on habitat and depth to look for new species and new records of nearshore coral reef fish species.

Material and Methods

The study area used for this research was the nearshore waters of Tutuila, American Samoa (14°S, 170°W) a U.S. territory in the South Pacific (Fig. 1). Tutuila, the largest island in the territory, exhibits

more diversified habitat types (coral reefs, lagoon, sand, mangroves, etc.) with more varied depths and bathymetric complexity than the other islands in the archipelago due mostly to its much greater size (Brainard et al 2008). Given the diversity of available habitat types, the broadest range of fish species should occur around this island.

Figure 1: Study site location, Tutuila, American Samoa.

Adapting the methodology described by Allen (2008), known point collection records (California Academy of Sciences, Australian Museum, Western Australia Museum, and the Bishop Museum) and verified field sightings data (various colleagues and NOAA-CRED) were used to analyze distribution patterns of nearly 3,000 nearshore coral reef fishes throughout the Pacific using GIS mapping software (ESRI, ArcMap 9.2). All pertinent collection information such as benthic habitat and cover types was reviewed. From these point data, polygons were created to connect points into a generalized equal area range map for each species (Fig. 2).

Figure 2: A representative equal area range map, in this case for *Iniistius pavo*, used for nearshore coral reef fish species presence predictions.

Equal area range maps were utilized in order to represent a true geographic relationship between collection points and theoretical range maps. It is very likely that there is a wider dispersal zone for each species around a given collection point, but for added conservativism, only exact locations were used to derive polygons without any type of buffer zone around individual point data. These range map polygons for individual species cover vast areas of the Pacific, most of which is deepsea/pelagic habitat. The distribution of individual reef species is assumed only to occur in areas with suitable habitat (e.g. nearshore shallow-water coral reefs and associated habitats). Species that were already known to occur (Wass 1984), were then removed from the dataset and the remaining species were examined. There were 138 species not previously recorded that had predicted ranges that included American Samoa or came within 400km of the Samoan Archipelago.

Using existing natural history data, habitat preferences for these species were identified. Taking species thought to occur in the territory from the data provided in the range maps, predictive habitat maps were then created for each of these species and their likely locations plotted using specific habitat parameters. Habitat parameters were derived for each species from the published literature utilizing known natural history and habitat useage (e.g. *Acanthurus olivaceus* occurs over coral and rubble bottoms, *Acanthurus lineatus* is most frequently encountered on shallow reef flats, while *Acanthurus thompsoni* is found near steep drop-offs). Habitat maps were created using orothorectified aerial photographs as well as IKONOS and Quickbird satellite data, following methodology developed by NOAA (Coyne et al 2003). The panchromatic visual imagery was first interpreted and reef zones delineated to classify major sub-types of reef (reef flat, slope, backreef, crest, and lagoon). Next Quickbird and IKONOS multispectral color imagery was used to delineate the nearshore area into broad classes of habitat (coral reef, plant, rock, sand). Each of these was then subdivided into narrower categories (i.e. emergent vegetation, macroalgae, seagrass, etc.). Output from the process of delineating the broad reef zones and habitat classes and their corresponding subclasses was a series of digital GIS layers. These polygons were then overlaid to produce a highly accurate and delineated thematic map of the nearshore benthic habitat. The overlay process involved adjusting the relative opacity for each individual map and then projecting each into the same plane so that multiple features could be viewed simultaneously. It was determined that an intersect operation did not identify subtle differences in the various layers and was therefore carried out visually to ensure accuracy of the interpretation. This process was repeated for each of the 138 predicted fish species. For example, *Iniistius pavo*, is known to occur at depths from 20-100m in areas with high sand near coral reefs with high rugosity. Bathymetric data

collected by the NOAA coral reef ecosystem division (Brainard et al 2008) was used to stratify the available habitats by depth. Given the size of the study location groundtruthing was not possible at all locations, therefore random sites were chosen and grountruthed using scuba. An accuracy rate of >90% was found at each of the 15 random sites. Exploratory dives were then made during the day and night into those likely habitats to look for the presence of predicted fish species. Additional survey dives were also carried out at historical collection sites and at various depths in these locations.

Results

Many fish species were found in American Samoa that were previously unrecorded. Most of these fish were species that are small, cryptic and/or nocturnal. There were however several species, including two stingrays, which attain significant sizes of 1m or more. These rays were found in sand flat habitats that have historically been undersampled (Fig. 3). Of the 138 fish predicted that had not been previously seen in American Samoa, 37 were located during this study, including one new family record. A further 10 fish species were located during the in-water survey dives which were unexpected (e.g. not predicted by the mapping procedures and previously unrecorded from Samoa). Of the 37 new species records, 34 were located in habitats previously poorly documented or searched. At least 3 species have been discovered which may be new to science including a Pomacentrid, Apogonid, and a Gobiid.

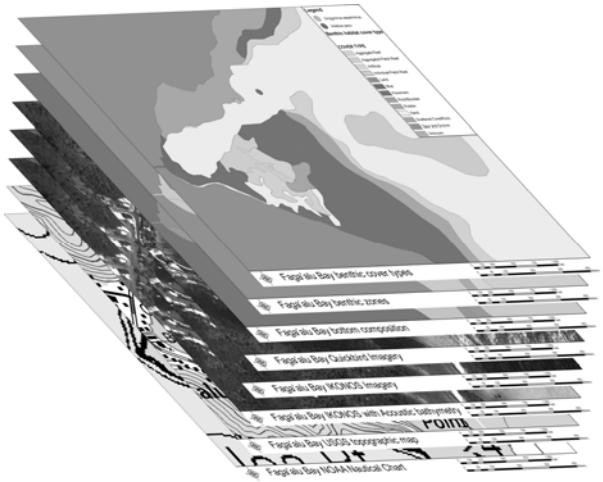

Figure 3: Multiple layers of benthic habitat maps, bathymetric data, and satellite imagery used to predict locations of predicted fish species.

Discussion

Many researchers, like recreational divers, often go to established sites. Given the limited time often available for studies, maximizing results by going to known locations is often prudent. This approach does however ignore certain habitats that may then get undersampled, if at all. Part of this study was focused on looking in those locations other researchers have deemed unfit or unworthy of limited research time. For example, Faga'alu Bay, within Pago Pago Harbor is often considered too degraded and impacted to be of any scientific value. Yet it is within this bay that many of the new species records were found.

Some new species records, like the two stingray species, are large and non-cryptic in nature and thus it is unlikely that they were present in previous years surveys and seem to indicate a recent colonization. While many species which were predicted were discovered, several others were found that were unexpected. This emphasizes the need for groundtruthing, as this was an important component of this study, not only to validate benthic habitat maps, but also to verify theoretical species presence and more significantly yielded 10 new unexpected records.

Given the small size, cryptic nature, and often nocturnal habits of the remaining predicted fish species, it is unlikely that using non-destructive sampling methods like those employed in the present study will uncover many additional species records from the predicted list. This study shows that using GIS based predictive modeling and non-destructive methods in novel habitats can yield advances in our knowledge of fish species in remote locations.

Acknowledgement

This project would not have been possible without the cooperation and data from various agencies; USFWS, USGS, NPS, NOAA Coral Reef Ecosystem Division, NOAA Biogeography, California Academy of Sciences, Australian Museum, Western Australia Museum, and the Bishop Museum.

An investigation of coral reef fish assemblage modelling with geostatistical methods

J. De Mazières[1], J. Comley[2]

1) School of Marine Studies, University of the South Pacific, PO Box 1168, Suva, Fiji Islands
2) Institute of Applied Science, University of the South Pacific, PO Box 1168, Suva, Fiji Islands

Abstract. The objective of this study was to determine the spatial distribution of reef fish assemblages according to the habitat types of the Coral Coast, Fiji by using geostatistical methods. The study focused on the reef flat zone covering 45 km² which was divided into 22 geomorphological reef units. Substrate and fish data were obtained from a previous field survey of 311 transects. We worked with five classes of habitats (sand, rubble, macroalgae, seagrass and coral) which were defined according to thresholds of 20% for the biotic substrate and 50% for the abiotic. Nine fish families were selected due to their importance for the fisheries and as reef health indicators. We conducted batches of multivariate statistical tests to identify significant patterns of fish assemblage distribution. Prediction maps of fish abundance were created by using the co-Kriging geostatistical model. Results showed that sand, seagrass and coral habitats hosted significantly different assemblages. The quality of the predictive models varied highly depending on the location and the fish family of which Acanthuridae and Scaridae showed the best accuracy. Reef fish modelling using a geostatistical approach provided encouraging results considering that this investigation was conducted with previously collected data and within a reduced resource context.

Key words: coral reef fish, assemblage, habitat, geostatistical modelling, Fiji

Introduction

Coral reef fish communities are influenced by the distribution and abundance of component species. Their distribution and abundance are in turn influenced by the interaction between their behaviour and the physical and biological environment. Many studies have shown that reef fish abundance and species richness are correlated with the biological nature of the substratum and notably with the extent of live coral cover (Bell and Galzin 1984; Chabanet et al. 1997; Garpe and Ohman 2003; Bouchon-Navaroa et al. 2005). However, habitat composition has not always been found as the main factor explaining fish community structures (Roberts and Ormond 1987; McClanahan and Arthur 2001; Dominici-Arosemena and Wolff 2005).

Although spatial models have been widely developed for terrestrial environments, they have just been recently applied to the marine ecosystems (Pittman et al. 2007). Most of the coral reef studies involving spatial modelling have mainly focused on assessing the effect of marine reserves on single fish species or assemblages (Núñez-Lara et al. 2005) and on improving the ecological knowledge of fish populations to support ecosystem-based management (Mellin et al. 2007; Pittman et al. 2007; Mumby 2006). As collecting data on extensive areas is regarded as too expensive and time costly, ecologists are now focusing on predictive methods and their improvement. Extrapolation is one of the approaches to predict patterns, where known data are projected, extended or expanded into an area not sampled based on assumptions of continuity and correlation among the variables (Miller et al. 2004).

Coral reefs are of crucial importance for the people of the Pacific Islands Countries since they support numerous economic and cultural activities in addition to providing environmental services. The Fiji Islands have been the location of many marine survey programmes providing a large quantity of data on reef benthic and fish assemblages. However, spatial analysis has been rarely if ever conducted and normal analysis has not been exhaustively carried out.

The main aim of this study is to model the spatial distribution of the reef fish assemblages according to the habitat types of the Coral Coast, Fiji Islands using geostatistical methods. The influence of the benthic composition on family taxa abundance is first assessed and then the feasibility of modelling reef fish distribution with the ArcGIS Geostatistical Analyst extension is investigated. Considering the Fiji context, where scientific resources are limited, this paper illustrates an experimental approach for coral reef research.

Material and Methods

Study Site

This study focused on the Coral Coast region located along the southwest coast of Viti Levu, Fiji's main island (Figure 1a). The Coral Coast is

bordered by the longest fringing reef found within Fiji's waters, stretching along about 80 km with a seaward extension of 500 m to 1 km. The reef system is made of 22 geomorphological reef units separated by channels.

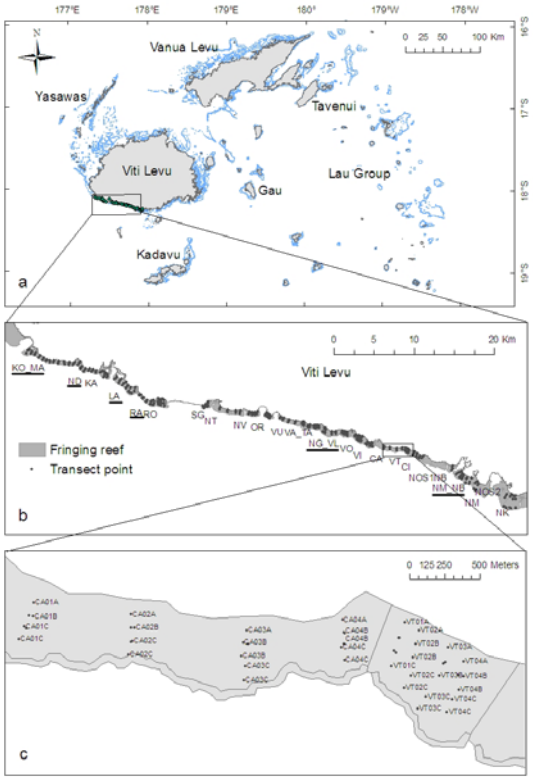

Figure 1: Study site. a) the Fiji Islands; b) the Coral Coast fringing reef and the sampling sites surveyed by CCC. Codes refer to the reef unit names. Underlined reef units were selected for modelling; c) close up showing the sampling design. Two points correspond to the start and end points of one 100 m section (named A, B or C).

The human population along the Coral Coast is distributed into villages of about 100 to 300 inhabitants with the exception of Sigatoka town where about 8,440 people live (Fiji Islands Bureau of Statistics 2007). With development and increasing population, the main threats to the ecosystem and its resources have been identified as being the overexploitation of fish and corals, inefficient waste management leading to coastal water pollution, and erosion and siltation due to inland deforestation (Thaman and Aalbersberg 2004).

Secondary Data and Benthic Habitat Classification

The field data used for this study were provided and collected by Coral Cay Conservation (CCC) between July 2004 and May 2005 (Rowlands et al. 2005) (Figure 1b-c). Data were collected along transects located perpendicular to the shoreline on the reef flat zone. Each transect was divided into three 100 m long sections which were laid down within three different zones of exposure to offshore influence. A total of 311 sections were surveyed by snorkelling based on a modified Reef Check technique. Assessment of benthic coverage was performed following the point intercept method along a 100 m tape. Substrate type was recorded every 0.5 m, providing a total of 200 data points per 100 m section. Fishes were counted along the same 100 m tape using the belt transect methodology applied within a 5 m wide by 20 m high box.

A hierarchical classification scheme of habitats was established *a priori* based on previous works and on expert knowledge. The classification scheme comprised of five habitat classes: sand, rubble, macroalgae, seagrass and coral. A simple quantitative component was incorporated with arbitrary percentage cover thresholds. Biotic substrates (i.e., coral, seagrass and macroalgae) were considered dominant when covering 20% of a transect, whereas a threshold of 50% was assigned to the abiotic categories (i.e., sand and rubble).

Multivariate Analysis

Multivariate statistical analyses were first conducted to identify significant patterns of fish assemblage distribution. Nine fish families (Chaetodontidae, Lethrinidae, Mullidae, Serranidae, Scaridae, Siganidae, Lutjanidae, Acanthuridae, Labridae) were studied due to their importance in terms of resources for the communities and their ecosystem health indicator status. Analyses were performed using the routines provided by the PRIMER v6 software (Clarke and Warwick 2001). Comparison of fish assemblage structures was based on the Bray-Curtis similarity coefficient. Investigation of the effect of habitat type on fish family abundance was done with the ANOSIM (ANalysis Of SIMilarity) significance test. To identify the characteristic families of each habitat type SIMPER (SIMilarity PERcentage) analysis was applied to the data, allowing identification of typical variables through calculating their average contribution to the intra-group similarity and to the inter-group dissimilarity.

Spatial Modelling

Modelling was based on the results of the multivariate analysis. Prediction maps of fish abundance were created at the reef unit scale, using the co-Kriging geostatistical model. The extrapolation is based on a trend identified from the data and the spatial autocorrelation theory assuming that features close to each other are likely to be more similar than the ones apart from each other. Co-Kriging is a stochastic model which provides an estimation of the variance for any point predicted. It is thus possible to quantify the quality of the surface models by measuring the statistical error of predicted surfaces. In addition, the co-Kriging model allows multivariate analysis where the predicted values are estimated according to the correlation with an influencing variable.

Several extrapolation models were tested by setting different parameters, such as the lag number and size, or the searching neighbourhood shape and methods (Johnson et al. 2001). They were compared using the cross-validation results. This provided information on the statistical performance of the model in predicting fish abundance values. A model was qualified as good if the mean prediction error is close to zero, the root-mean-square standardized prediction error is close to one and the root-mean-square prediction error is small. These measurements indicate, respectively, unbiased predictions, accurate standard errors and predicted values similar to the measured values (Johnson et al. 2001). The models with the lowest statistical errors obtained for each family and reef unit were then selected and the surface maps were converted into polygon layers.

Results

Fish-Habitat Associations

Exploratory analyses and statistical tests showed that fish assemblages were structured differently among different habitat types (Table 1). Differences were highly significant for macroalgae vs. sand (p=0.001), seagrass vs. coral (p=0.001) and rubble vs. sand (p=0.003). In addition, fish assemblages found within coral and within rubble habitats had significantly different structures compared to those associated with sand and seagrass dominated areas respectively.

Table 1: Results of the ANOSIM analysis. Global R=0.116 and p=0.001. Confidence intervals are represented by asterisks as follow: * 95%; ** 99.9%. Only significant results are shown here.

Pair-wise tests	R value	p value
macroalgae vs. sand	0.46	0.001**
seagrass vs. coral	0.558	0.001**
rubble vs. sand	0.291	0.003**
coral vs. sand	0.182	0.026*
rubble vs. seagrass	0.169	0.044*

According to the SIMPER analysis, the average contribution of the family to the intra-group similarity showed two patterns of association family-habitat (Figure 2). Labridae contributed at 95% to the similarity within the seagrass group and was thus considered as a discriminating family. In addition, given their high percentage contributions, Scaridae and Acanthuridae can be considered as discriminating families of the groups seagrass vs. coral and coral vs. sand.

Labridae had the highest contribution to the inter-group dissimilarity and the order of percentage contribution of the families was the same in all of the pair-wise results (Table 2). Dissimilarity of fish assemblages between macroalgae and sand habitats was due to the high abundance of Labridae in sand areas. Three pair-wise tests (macroalgae vs. sand; rubble vs. sand; rubble vs. seagrass) showed that the contribution to the dissimilarity was dominated by Labridae while in the two others (seagrass vs. coral; coral vs. sand), the contribution were more evenly distributed among Labridae, Scaridae and Acanthuridae families. Given their high percentage contributions, Scaridae and Acanthuridae can be considered as discriminating families of the groups seagrass vs. coral and coral vs. sand.

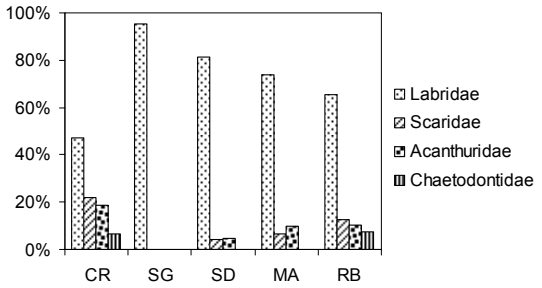

Figure 2: Average contribution of the fish families to the intra-group (habitat type) similarity. CR: coral; SG: seagrass; SD: sand; MA: macroalgae; RB: rubble

Spatial Prediction of Fish Abundance

Surface predictions of abundance were created for the three families which displayed the strongest patterns in their relationship with habitat types: Labridae, Acanthuridae and Scaridae. Labridae distribution was predicted at two reef units, NM_NB and RA (Figure 1), where seagrass habitats have been mapped. Modelling of Acanthuridae and Scaridae abundance was performed based on coral cover and thus at four reef units (KO_MA, LA, ND and NG_VL). Models including data on the three biotic habitats (seagrass, macroalgae and coral) were also developed in order to investigate whether considering additional habitat characteristics improved the results.

Table 2: Percentage contribution of family to assemblage dissimilarity between habitat types.

Family	rubble vs. seagrass	seagrass vs. coral	macroalgae vs. sand	rubble vs. sand	coral vs. Sand
Labridae	45.21	30.96	52.57	48.07	37.75
Scaridae	19.96	26.54	14.93	19.55	24.32
Acanthuridae	14.07	23.73	13.5	12.94	20.41
Chaetodontidae	7.49	6.84	7.42	7.94	6.29
Siganidae	6.15	4.33	5.6	4.91	3.98

Table 3: Results of the cross-validations of the fish abundance models which showed the lowest statistical errors. Models based on "3 habitats" included seagrass, macroalgae and coral covers.

Model	Reef unit	Mean error	Root-mean-square	Average standard error	Mean standardized	Root-mean-square standardized
Labridae + Seagrass	RA	0.236	63.39	62.76	0.006	1.018
Acanthuridae + 3 habitats	ND	0.008	22.18	23.08	0.001	0.962
Scaridae + 3 habitats	ND	0.055	17.65	17.96	0.002	0.987

Comparison between the models using cross-validation showed that the quality of the models was highly variable among families and reef units (Table 3). Surface prediction of Labridae abundance appeared to be more difficult to create with high accuracy since the models were not satisfactory with mean prediction errors ranging from -1.546 to 0.236. However, prediction was best fitted at RA when only seagrass was included in the model.

Models of Acanthuridae and Scaridae seemed to provide better results at some locations. The best mean prediction errors were for both families found at ND. Considering the models of Acanthuridae, the best model predicted abundance with an average standard error of 22 at ND. This uncertainty appeared to be overestimated since the root-mean-square standardized error was less than one (0.962). It seemed that the model quality was slightly improved with the integration of the three biotic habitat types. Mean prediction error of Scaridae abundance was lowest at ND with the coral based model. However, Scaridae abundance was estimated with an average standard error of 18 at ND based on the three habitat covers. The root-mean-square standardized error was 0.987 indicating a better assessment of the variability though there remained an apparent overestimation of abundance. Cross-validation results showed that Acanthuridae and Scaridae predictions were of better quality when they were based on the three-habitat model while Labridae model was best fitted with the one-habitat model.

Discussion

The modelling of selected fish families using geostatistical methods provided contrasting results depending on the site and the families. It appeared that models were likely to create accurate surface predictions of abundance at one specific reef unit (ND) for one family (Acanthuridae). It is possible that the level of spatial autocorrelation in reef fish distribution was too low to provide accurate models. Reef fish distribution is influenced by spatial, temporal and behavioural factors which might have also affected the level of accuracy. In addition, the number of samples was a constraint preventing the modelling of fish abundance at several reef units. It suggests that additional field data may improve the model accuracy but it compromises the intent of the method which is to obtain results with already available data. Prediction maps of Scaridae and Acanthuridae showed a narrow range of abundance variation across the reef unit (Figure 3). Such patterns are unlikely to occur in reality and when the predicted values were compared with the measured ones, the variation was not reflected within the former. However, the results need to be compared with the reality of the field.

It has been argued that the tendency of the fish species to move and migrate influences the results of spatial variation models (Ault and Johnson 1998). They found that the best predictive models of fish density occurred for site-attached species such as the members of the Pomacentridae (Damselfish) family.

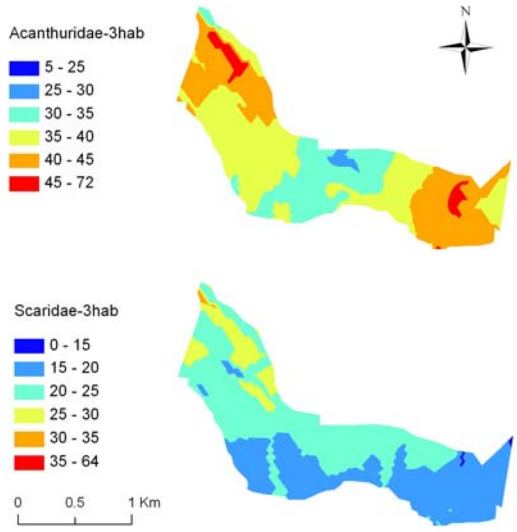

Figure 3: Surface predictions produced by the two statistically best co-Kriging models of the Scaridae and Acanthuridae abundances at the ND reef unit.

Reef ecologists first conducted their research with the notion that fish communities were organized in an equilibrium system to later shift toward an approach which comprehends reef fish communities as an open non-equilibrium system (Sale 1991). Owing to the difficulty in drawing general patterns in reef fish community organization, ecologists have for some time accepted that reef fish assemblages were driven by

stochastic processes. Recent research has increasingly shown that the habitat utilization by reef fishes was not a random process (Ault and Johnson 1998; Friedlander et al. 2007; Garpe and Ohman 2007).

If reef fish assemblages are non-equilibrium systems which develop within a dynamic environment, their modelling can be done through simulation models (Guisan and Zimmermann 2000). However, this needs a high level of understanding of the relationship between assemblage and habitat. For instance, spatial extrapolation methods encompass the determination of the scale effect on the response variable, in this case on the fish assemblage structures (Miller et al. 2004). It thus appears necessary to gain a good understanding of the scale-dependence of the reef fish assemblages in order to reach accurate predictions. Yet again it implies a design of sampling methodologies allowing the estimation of the scale effect on the results.

Modelling of reef fish assemblages using geostatistics showed some satisfactory results in selected taxa and defined geographic areas. However, the outcomes of this investigation suggested that geostatistics applied to reef fish ecology could provide better results if used to define sampling design for a non-parametric spatial approach. In addition, there is a need to deepen the investigation of the Coral Coast reef fish assemblage patterns and processes. By examining the impacts of other influencing factors such as the habitat complexity and human pressure, the model results could be improved. Integrating human pressure could be based on the fishing pressure gradients documented by previous studies done in Fiji (Jennings and Polunin 1995; Dulvy et al. 2004). Study on the temporal variation and the recruitment effects would be of great interest but would be more costly in terms of time and funds. Similarly, the model may be improved by basing it at the species level which would allow the examination of other indicators such as species richness, biomass and more clearly defined feeding, ecological and behavioural guilds.

This investigation provided encouraging results considering that it was conducted with previously collected data and considering the Fiji context where resources are limited. Moreover, it demonstrated to local scientists and practitioners the potential of Geographic Information System and spatial analysis to coral reef science and management.

Changes in spectral reflectance in response to salinity variation in *Siderastrea radians* from Florida Bay, Florida USA

M.J. Durako[1], K.M. Chartrand[1]

1) The University of North Carolina Wilmington, Department of Biology and Marine Biology, Center for Marine Science, 5600 Marvin Moss Ln, Wilmington, NC 28409 USA

Abstract. Spectral reflectance (*R*) of coral reefs is an apparent optical property that is widely used to distinguish these communities in remote sensing assessments. In this study *R*'s of *Sidereastrea radians* collected from five basins in Florida Bay were measured at the termination of a 2-week salinity (30, 20, 15, 10) versus population mesocosm experiment. The five basin populations represented a spatial and freshwater-land influence gradient from northeast (estuarine-to-hypersaline) to southwest (marine) Florida Bay. Spectral reflectances generally increased with decreased salinities with the greatest increases occurring in the more marine populations. The marine populations also exhibited the "brown" reflectance spectra mode while the more estuarine populations exhibited predominantly "blue" reflectance spectra. Two of the interior basin populations exhibited spectral shifts from "blue" to "brown" in response to low salinity treatments. Non-metric multidimensional scaling analyses indicated stronger salinity-based versus population-based clustering of the reflectance spectra. Thus, while coral *R* may be independent of taxonomic or geographic differences, reduced salinity does affect this parameter in *S. radians* from this marginal coral habitat.

Key words: Spectral reflectance, salinity, *Siderastrea*.

Introduction

The health of corals may be assessed using a number of metrics (i.e., growth, reproduction, metabolism, etc.), but loss of zooxanthellae or their pigments is the only remotely detectable measure of coral health because of the resulting changes in their spectral reflectance (Holden and LeDrew 1998, 2001). Spectral reflectance (*R*) of corals is an apparent optical property that is also widely used to distinguish these communities and monitor their status in remote sensing assessments (Green et al. 1996; Karpouzli et al. 2004). The magnitude and shape of coral *R* spectra are generally distinct from other benthic communities and bare sediments (Hochberg and Atkinson 2000), but independent of within-coral geographic and taxonomic differences (Hochberg et al. 2004). There are generally two spectral shapes of coral *R*, the "brown" mode, which is determined by zoothanthellae pigment absorption, and the "blue" mode, which includes expression of a coral host pigment. Reflectance spectra of stressed or bleached corals are generally higher and optically different than those of healthy corals, due to the loss of zooxanthellae pigments (Holden and LeDrew 1998).

Siderastrea radians (Pallas) Blainville is a hardy coral found throughout the tropical western to eastern Atlantic and Caribbean region that inhabits so-called marginal habitats away from characteristic reef communities (Veron 2000). In Florida Bay, this species occurs in areas of little sediment and low abundance of seagrasses (Figure 1). Concern over the long-term health of the Florida Bay ecosystem and the adjacent Everglades led to the Comprehensive Everglades Restoration Plan (CERP). One of the primary goals of CERP is to restore estuarine conditions in the Bay by increasing the quantity and quality of freshwater entering Florida Bay, which will lower salininties. The effects of reduced salinity on coral communities within Florida Bay have largely not been considered. Coral stress or bleaching may occur in response to decreases in salinity (Hoegh-Guldberg 1999), thereby affecting *R*.

In this study *R*'s of *Sidereastrea radians* collected from five basins in Florida Bay were measured at the termination of a 2-week salinity (30, 20, 15, 10) versus population mesocosm experiment designed to examine the salinity tolerance of this species. The five basin populations examined represented a spatial and freshwater-land influence gradient from northeast (estuarine-to-hypersaline) to southwest (marine) Florida Bay (Figure 1). The experimental salinities were chosen to encompass the range of salinities that occur across these five basins.

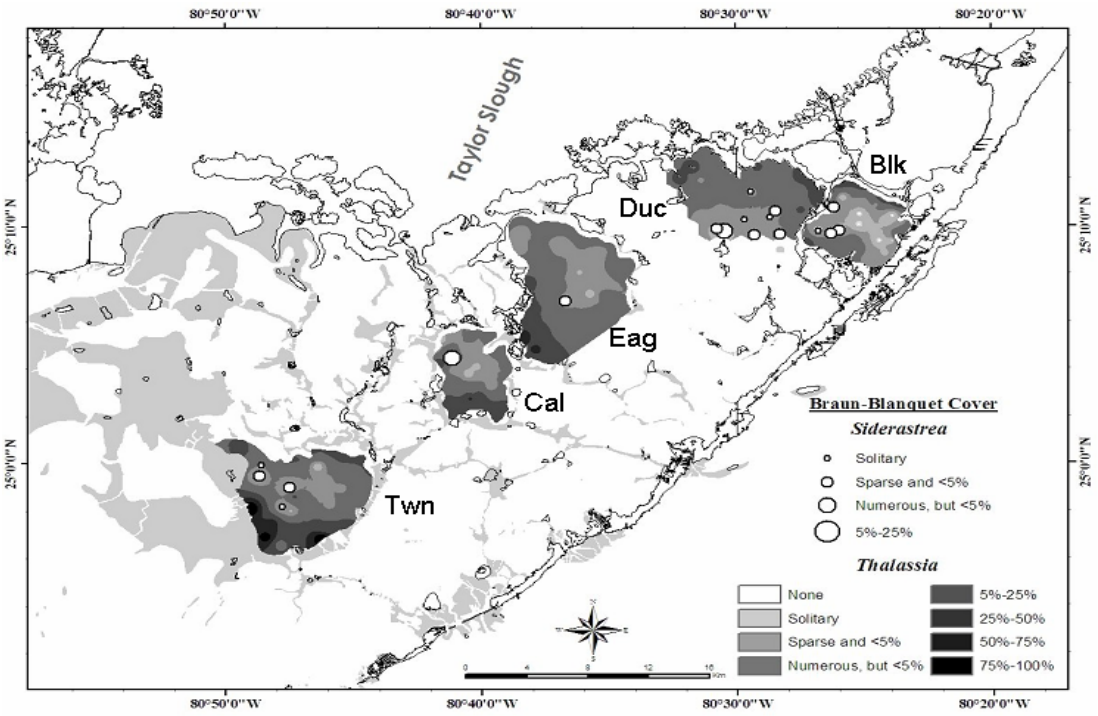

Figure 1 Distribution of *Siderastrea radians* and *Thalassia testudinum* in Florida Bay.

Materials and Methods

During Fall 2006 Fish Habitat Assessment Program (FHAP) field surveys, sixteen *S. radians* colonies (≤3-5 cm in diameter) were collected per basin from locations where the highest colony densities were previously observed. The five sampled basins, from northeast to southwest, were Blackwater Sound (Blk), Duck Key (Duc), Eagle Key (Eag), Calusa Key (Cal) and Twin Key (Twn) Basins (see Figure 1). Colonies were transported to the greenhouse at the University of North Carolina Wilmington, Center for Marine Science (CMS), Wilmington, NC overnight. Care was taken to ensure colonies were never removed from seawater and that temperatures and salinity were maintained under near-ambient field conditions.

Colonies were placed in 40-1 aquaria filled with high quality seawater and containing gravel-bed filter aeration systems. One colony per basin was randomly chosen and placed in each of 16 aquaria. Location was randomly assigned yet placement ensured that a colony from each basin was in each tank position at least twice. After one week acclimation at a salinity of 30 (the average salinity ±1 at collection sites), target treatment salinities of 10, 15, 20, and 30 (controls) were assigned to each of 16 aquaria (n=4, level of replication is the tank). Salinities were decreased daily by adding distilled water to experimental tanks to drop salinity at a rate of 2 day^{-1}. This rate of change was chosen to represent a realistic drop in salinity in the Bay during flushing and/or rainfall events (Kahn and Durako 2005, 2006). We measured *R* of the dorsal surface for all coral colonies 4 days after the lowest salinity treatment target was reached.

Reflectance (bi-directional) is the fraction (%) of downwelling radiance that reflects upward as a function of wavelength (λ) [$R(\lambda) = L_u(\lambda)/L_d(\lambda)$]. Radiance measurements employed an Ocean Optics USB2000 fiber optic spectrometer coupled to a 400 μm diameter UV-VIS reflection probe (Ocean Optics QR400-7-UV-VIS). To measure upwelling radiance [Lu(λ)], the probe was positioned 1 cm above the coral dorsal surface at a 45^o zenith angle (Hochberg and Atkinson 2000). Immediately following, downwelling radiance [Ld(λ)] was measured using a Spectralon diffuse reflectance target (Ocean Optics WS-1) placed adjacent to, and in the same plane as, the coral. It was assumed that the Spectralon target is Lambertian (i.e., reflects light equally in all directions).

Results

Reflectance spectra for the control treatment corals (salinity 30) exhibited a brown mode triple-peaked pattern (570, 600 and 650 nm) for the Blackwater Sound, Calusa Key and Twin Key Basin populations and a blue mode plateau between 600 and 650 nm in the more interior Duck and Eagle Key Basin populations (Figure 2, *sensu* Hochberg et al. 2003). Spectral reflectances generally changed little or increased slightly at the decreased salinity of 20, with

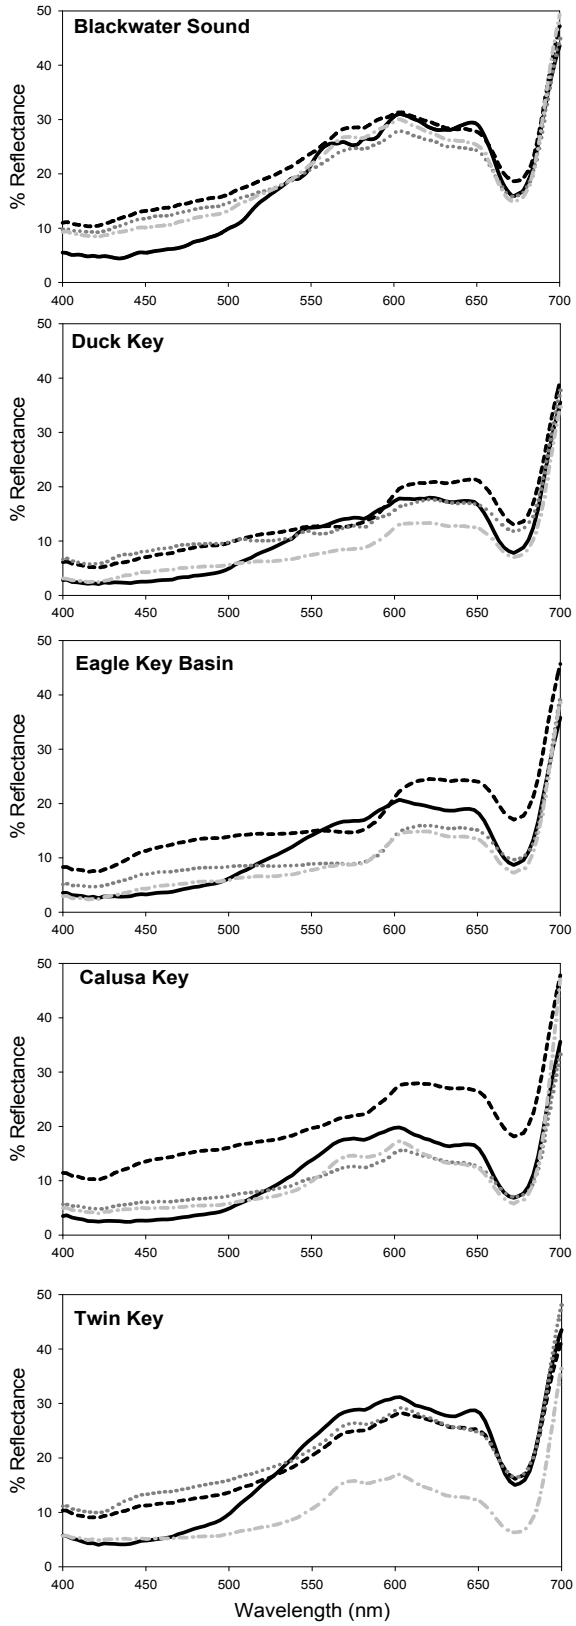

Figure 2. Reflectance spectra of *S. radians* from 5 Florida Bay basins in four salinity (10=black solid, 15= black dash, 20=grey dots, 30=grey dot-dash) treatments (n=4).

the greater increases in *R* occurring in the 15 and 10 salinity treatments. At the lowest treatment salinity (10), reflectance patterns were quite distinctive spectrally and exhibited differing population patterns. For all five populations, reflectance was generally lowest in the salinity 10 treatment at wavelengths <500 nm, but was highest at wavelengths >500nm for the most marine populations (Twin Key Basin). *R* was relatively high across PAR in the salinity 15 treatment for the three interior basin populations (Duc, Eag, and Cal, Fig. 2). Two of the estuarine basin populations (Eagle & Calusa) exhibited spectral shifts from blue mode to brown mode *R* in response to changes in salinity.

Non-metric multidimensional scaling analyses indicated that reflectance spectra exhibited similarities based on treatment salinity, with high- (30), intermediate- (20 and 15) and low-salinity (10) groupings (Figure 3). There was generally weak population-based clustering. The exception was the Blackwater Sound population which exhibited highly-similar reflectance spectra across all salinity treatments, except 10 (Figures 2 and 3).

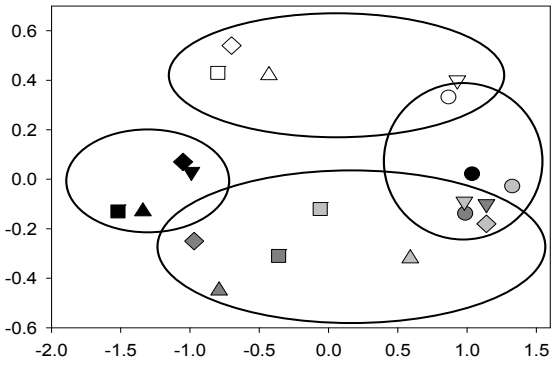

Figure 3. Two-dimensional MDS ordination of reflectance spectra similarity matrices among five populations (●=Blk, ■=Duc, ▲=Eag, ♦=Cal, ▼=Twn) of *S. radians* exposed to four salinity treatments (white=10, light grey=15, dark grey=30, black=30).

Discussion

The magnitude and spectral shape of coral spectral reflectance (*R*) are determined by absorption and fluorescence of several pigments localized in both the zooxanthellae and the host tissues (Hochberg et al. 2004). Healthy corals are optically dark and generally exhibit low *R* between 400-500 nm, increasing from 500-650 nm with a narrow chlorophyll absorption feature near 675 nm, then rapidly increasing at wavelengths greater than 680 nm (Holden and LeDrew 1998; Hochberg et al. 2004). Changes in environmental factors, such as temperature or salinity, may cause decreases in various pigment concentrations or expulsion of zooxanthellae from the coral host leading to spectral shifts and an overall increase in *R*. Thus, spectral distinctions between

healthy and non-healthy corals can be based on changes in the shape and magnitude of reflectance (Holden and LeDrew 1998, 2001).

Changes in *R* of *Siderastrea radians* from Florida Bay in response to experimental step-wise decreases in salinity indicate a high tolerance to hyposalinity stress, with a tolerance threshold between salinities of 10 and 15. Coles and Jokiel (1992) state that salinities below 15 sustained for more than two days will lead to coral mortality. That does not seem to be the case here as our measurements were obtained after four days at salinity 10 and six days at salinity of 15. Other coral species from coastal environments with fluctuating salinities, similar to Florida Bay, have also demonstrated tolerance to reduced salinities (Marcus and Thornhaug 1981, Muthiga and Szmant 1987, Manzello and Lirman 2003). *Siderastrea radians* from Blackwater Sound exhibited almost no change in *R* until salinity of 10 was reached and mainly below 500nm. *R* was elevated across PAR in the salinity 15 treatment for the two most interior basins (Eag and Cal). Blackwater Sound is a diverse basin with widely fluctuating salinities due to the influences of freshwater inflow from the Everglades via the C-111 canal and oceanic influences due to several cuts connected to the Atlantic Ocean (Hackney and Durako 2004). The small increases in *R* with decreasing salinities in the other four populations do suggest some loss of zooxanthellae pigments, but no bleaching of the colonies was observed. In addition, chlorophyll fluorescence measurements (F_v/F_m) indicated symbiont health was not acutely affected by decreasing salinities until a threshold was reached between salinities of 10 and 12, a salinity drop of roughly 20 from ambient (Chartrand 2008).

Different populations of *S. radians* across Florida Bay exhibited differing modes of *R*. At high salinity, three populations exhibited the brown mode *R* and the two most interior populations exhibited the blue mode *R*. Zooxanthellae pigments are responsible for the 575 nm peak characteristic of brown mode *R* (Hochberg et al. 2003). Coral-host pigments are thought to have strong absorbance in the 560-570 mn region leading to a loss of the 575 nm peak and production of a plateau-like shape from 600-650 nm that is characteristic of the blue mode *R*. Many coral taxa exhibit both blue- and brown-mode *R* that depend on the concentration of the coral-host pigmentation relative to that of the zooxanthellae (Hochberg et al. 2004). The shifts from "blue" or "brown" spectral shapes of *R* with decreasing salinities in two of the more estuarine populations that we sampled may indicate differing among-population salinity tolerances between the zooxanthellae and the coral host for *S. radians* occurring in different basins across Florida Bay. Thus, while coral *R* may be independent of taxonomic or geographic differences, reduced salinity does affect this parameter in *S. radians* from this marginal coral habitat and thus may provide a non-invasive metric for the health of this species within Florida Bay.

Single-beam acoustic remote sensing for coral reef mapping

A.C.R. Gleason[1], R.P. Reid[1], G.T. Kellison[2]

1) Div. Marine Geology and Geophysics, U. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149
2) National Marine Fisheries Service, SEFSC, 75 Virginia Beach Dr., Miami, FL 33149, USA

Abstract. Several commercial single-beam acoustic seabed mapping systems have come to market in the last decade, but the potential for mapping coral reef habitats with these systems has not been systematically documented. Three datasets from the Florida Keys, USA, and the Bahamas, all acquired by a Quester Tangent Series V (QTCV), revealed that rock and sediment were reliably distinguished across multiple survey sites with accuracy ranging from 74%-86%. The utility of a simple rock/sediment classification scheme for assessing fish habitat and for objectively mapping habitat based on patchiness and relief metrics are discussed.

Key words: Acoustic seabed classification, QTC, fish habitat.

Introduction

Coral ecosystems that cannot be mapped with aerial or satellite imagery are both extensive and ecologically important. For example, over 55% of the Florida Keys National Marine Sanctuary (about 1540 square nautical miles) has not been mapped due to water depth or clarity limitations (FMRI 1998).

Acoustic systems are the natural solution for mapping areas where the seabed is not visible from overhead imagery. Single-beam, multibeam, or sidescan systems each may be used for acoustic seabed classification (Michaels 2007). The advantages of single-beam systems include relatively low costs, low data volumes, and easy portability.

Several studies have used commercial single-beam systems to map coral reefs (Hamilton et al. 1999; White et al. 2003; Moyer et al. 2005; Riegl and Purkis 2005; Riegl et al. 2007), but basic questions about what substrates can be reliably distinguished and how consistent classification schemes are in different areas have not been systematically explored. This project used a Quester Tangent Corporation (QTC) system to begin answering such questions.

Most evaluations of remote sensing technology or processing algorithms use data from a single study site. In contrast, the approach taken here was to compare results across multiple study sites in order to assess what seabed types could be mapped reliably by QTC across a variety of coral reef environments.

The objective was to determine what acoustic seabed classes were consistently distinguished across survey areas. The strategy used was to survey multiple sites using the same equipment, cluster the acoustic data from each site independently, and compare the accuracy of the resulting classifications.

Methods

The 50 kHz QTC Series V (QTCV) system described by Gleason et al. (2006) was used to acquire acoustic data during three surveys.

The first survey was conducted in the vicinity of Lee Stocking Island (LSI), Bahamas, on 16-20 June 2001 (Fig. 1). Approximately 145 km of track lines were surveyed along the bank top in water depths ranging from less than one meter to just over 10 m.

The second survey was conducted on 14 and 28 March, and 4 April 2002 offshore of Carysfort Reef, in the Florida Keys (Fig. 1). Fifty-two parallel transects, with a combined length of 124 km, were run across the upper shelf at depths of 3-35 m. This survey was described by Gleason et al. (2006).

The third survey was conducted at Fowey Rocks, also in the Florida Keys, about 45 km north-northeast of Carysfort (Fig. 1). The Fowey survey was conducted 12 and 20 October 2003 and included forty-one parallel transects, with a combined length of 72 km, across the upper shelf at depths of 3-40 m.

Acoustic data were processed with the IMPACT software package (version 3.4, QTC, Sidney, BC, Canada, 2004). Details of the IMPACT processing have been previously published (e.g. Preston et al. 2004; Gleason et al. 2006; Freitas et al. 2008). For the purposes of this paper, the key point regarding IMPACT is that the input to the program consisted of the raw echoes recorded by the QTCV and the output from the program consisted of: a) the optimum number of clusters into which the echoes should be split (as defined by Preston et al. 2004), and b) a label for each echo assigning it to one of the defined clusters.

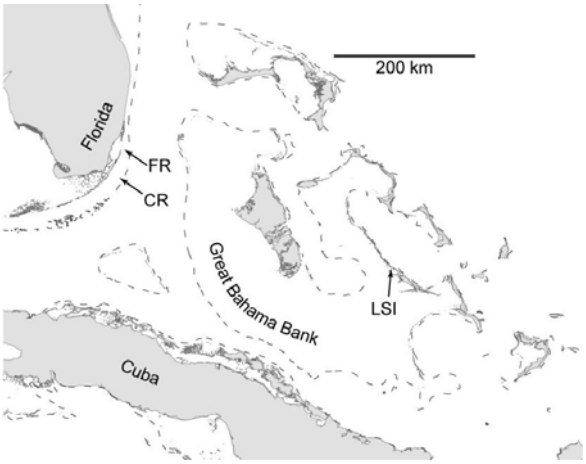

Figure 1: Location of Lee Stocking Island (LSI), Carysfort Reef (CR) and Fowey Rocks (FR) sites. Dashed line is the 200m isobath.

IMPACT's auto-clustering routine divides a dataset into distinct clusters based on echo shape, but, like any unsupervised classification routine, it cannot give these clusters descriptive names (e.g. reef, rubble, seagrass etc..). The clusters output from IMPACT, therefore, must be labeled by reference to other data sources. Cluster labeling for these surveys employed: comparison to satellite imagery, notes taken while snorkeling or drift diving, examination of the mean echo shapes for each cluster, bathymetric cross sections, and reference to previous seabed classifications at these sites (Gonzalez and Eberli 1997; FMRI 1998; Lidz et al. 2003; Louchard et al. 2003; Mobley et al. 2004).

Once the acoustic clusters had been labeled, they were quantitatively compared with "ground truth". The ground truth datasets acquired at each site were independent of the qualitative observations used for cluster labeling. Two types of data were collected for assessing the accuracy of the acoustic classification. Downward looking video images were acquired during the LSI survey, which was shallow enough and in clear enough water that the seabed was always visible from the surface. In contrast, the seabed was not visible from the surface at all times during the Carysfort and Fowey rocks surveys, due to deeper and less clear water. Therefore, at Carysfort and Fowey diver-based observations were acquired.

The video from the LSI survey was acquired with a Sony TRV 900 camera in an underwater housing that was mounted to the same pole that supported the transducer used for the survey (Fig. 2). Video was acquired in time-lapse mode, so that an entire day's worth of surveying could fit on one video tape. In time-lapse mode, the camera was set to acquire video (at full frame rate) for two seconds and then to pause for 28 seconds.

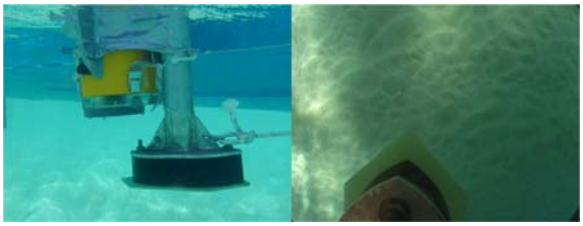

Figure 2: Left: Underwater photograph of pole-mounted transducer and video camera housing, as used for the LSI survey. Right: Sample frame grabbed from the video over a sandy seabed.

The entire LSI video data set consisted of 1502 two-second long clips. A single frame was extracted from each clip for analysis. For each frame, an analyst estimated the percent of rocky and sandy substrate. At the beginning of the day, the camera's clock was synchronized with a GPS unit. Using the time code embedded with each frame, the locations of the frames were determined from daily GPS tracks.

The diver-based observations collected at Carysfort Reef (N=22) and Fowey Rocks (N=15) followed the Bohnsack and Bannerot (1986) stationary reef visual census (RVC) method. The RVC protocol focuses on the collection of fish population data, but habitat data, including estimates of the percent of the seabed covered by rock, rubble, and sediment, are also collected (McClellan and Miller 2003). Estimates of substrate are the portion of the RVC dataset used for this analysis.

An error matrix (Congalton and Green 1999) was constructed for each survey site for comparison of the acoustic classification with the video/diver estimates of substrate. The comparison was made between each ground truth sample and the closest acoustic echo to that point. One refinement of the standard error matrix technique was necessary. The video/diver data was expressed as a fraction; the substrate at each point was X% sediment, Y% hard bottom, and Z% rubble. The acoustic classes, on the other hand, were discrete, so each entry in the error matrix was divided proportionally by the video/diver-estimated substrate (Gleason et al. 2006 have a sample calculation.)

Results

The LSI data clustered into nine acoustic classes. Only four of these classes, however, made up 96% of the total number of echoes. The cluster labeling process indicated that one of the acoustic classes, with 26% of the echoes, corresponded to hard bottom while the other three classes, with combined 71% of the echoes, corresponded to sediment. Comparison with the LSI video dataset indicated that the hard bottom/sediment acoustic classification had an overall accuracy of 74% (Fig. 3).

The Carysfort data clustered into seven acoustic classes. Only three of these classes, however, made

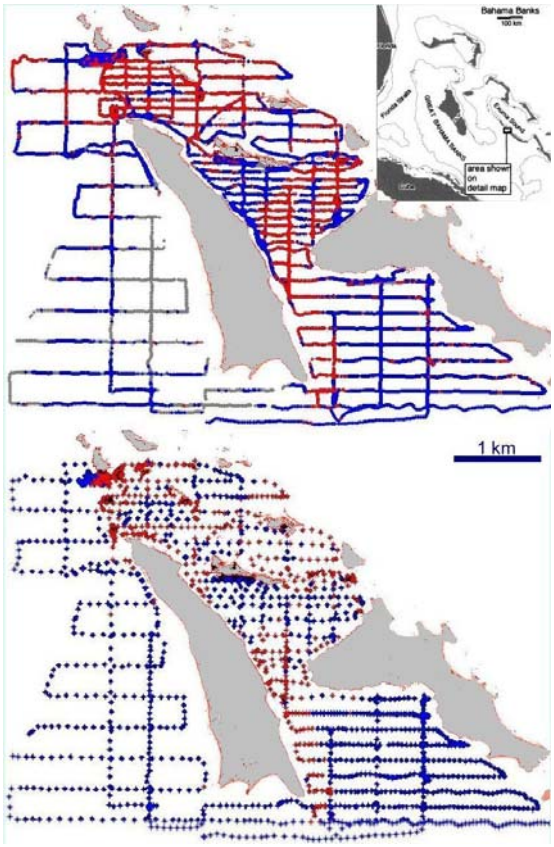

Figure 3: LSI acoustic classification (top) and video classification (bottom). Red and blue points in both plots indicate hard bottom and sediment, respectively. The two additional sediment classes in the acoustic classification are shown in grey (top). Islands are shown in grey in both plots.

up 94% of the total number of echoes. The cluster labeling process indicated that one of the acoustic classes, with 46% of the echoes, corresponded to hard bottom while the other two classes, with combined 48% of the echoes, corresponded to sediment. Comparison with the RVC substrate dataset indicated that the Carysfort hard bottom/sediment acoustic classification had an overall accuracy of 86%.

The Fowey Rocks data clustered into six acoustic classes. Only four of these classes, however, made up 97% of the total number of echoes. The cluster labeling process indicated that two of the acoustic classes, with combined 63% of the echoes, corresponded to hard bottom while the other two classes, with combined 34% of the echoes, corresponded to sediment. Comparison with the RVC substrate dataset indicated that the Fowey Rocks hard bottom/sediment acoustic classification had an overall accuracy of 78% (Fig. 4).

Discussion

The results showed that rock was well discriminated from sediment using the QTCV. Overall accuracy for the rock/sediment classification in the three surveys ranged from 74% to 86%. Many maps with a coarse level of descriptive resolution that were derived from satellite imagery have overall accuracy in this same range (Mumby et al. 1997; Andrefouet et al. 2003).

It is worth considering whether a rock/sediment classification scheme is too simple to be useful. Even though the overall accuracy of the simple two-class acoustic seabed maps was comparable to coarse-level maps derived from satellite imagery, most image-derived seabed maps have more than just two classes. One difference between satellite or aerial imagery and acoustic data is that bathymetry is inherently part of the acoustic data collection, and is therefore available to complement the seabed classification. Adding even a simple rock/sediment classification to traditional bathymetric data has a strong potential to benefit habitat mapping.

One example of the benefits of adding a simple rock/sediment classification to traditional bathymetric data for habitat mapping is the ability to discriminate outcropping parts of the seabed. Hard bottom is known to be important habitat for many types of fish. Sometimes substrate can be inferred from topographic profiles, but in other cases interpreting the bathymetry alone can be misleading. Figure 5 shows an example from the Florida Keys where bathymetry alone provided a misleading picture of habitat.

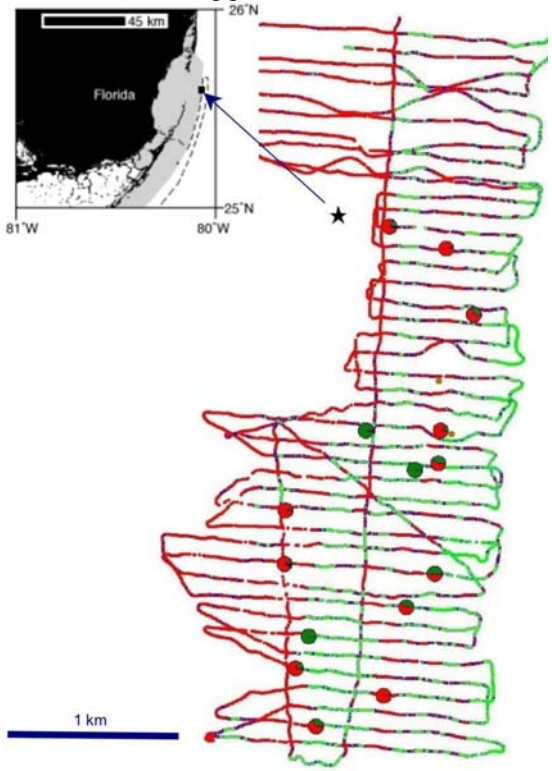

Figure 4: Fowey rocks acoustic classes (track lines) and diver estimated substrate (pie charts). Red and green represent hard bottom and sediment substrate for both types of symbols.

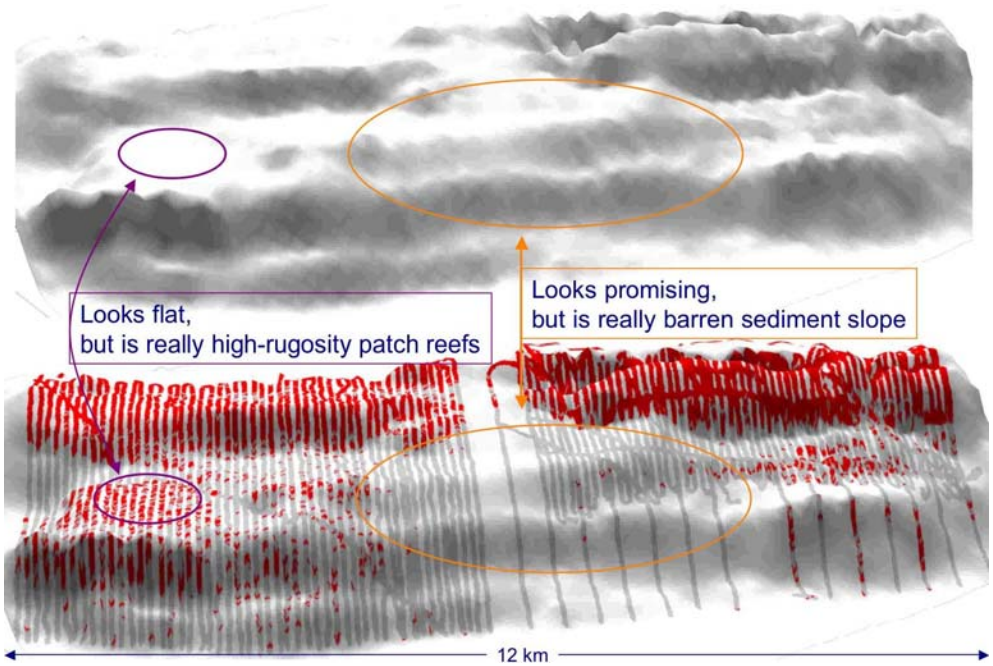

Figure 5: Example of the utility of rock/sediment seabed classification in interpreting bathymetry for fish habitat. Top panel: sunshaded bathymetry from single-beam echosounder depths interpolated to a 30 m grid along the upper slope seaward of Carysfort and Watson's Reefs, Florida Keys, USA. Bottom panel: Survey track lines superimposed on the same sunshaded bathymetry as the top panel. The track lines are colored red for hard bottom (rocky) and gray for sediment substrate. In both panels, oblique view is from the ESE, total along shelf distance is about 12 km, and depth ranges from 3 to 60 m.

Based on bathymetry alone (Fig. 5, top), the area in orange appears to be promising fish habitat because it contains two parallel ridges with steep slopes, and the area circled in purple appears to be a flat, featureless plain. When considering seabed type in addition to bathymetry (Fig. 5, bottom), a different interpretation becomes apparent; sediment covered the area in orange, providing little shelter for fish, while the area in purple was covered with small patch reefs, which would generally provide excellent reef fish habitat.

A second benefit to habitat mapping resulting from the addition of a simple rock/sediment classification to bathymetry is the potential to create an objective habitat classification scheme based on patchiness and relief. Franklin et al. (2003) proposed such a habitat classification scheme for coral reef environments. Patchiness was defined as the percent of the seabed within a certain radius of the point being classified that was covered with sediment. Relief was defined as the depth range within a certain radius of the point being classified.

Miller et al. (2008) used QTCV data and the Franklin et al. (2003) classification scheme to produce a benthic habitat map for the Navassa National Wildlife refuge. One of more than 100 transects used to create the Miller et al. (2008) map is shown in Figure 6; it illustrates the potential of QTCV data as input to the Franklin et al. (2003) classification scheme. The top portion of Figure 6 shows the transect plotted with echoes colored by substrate, while the bottom shows the transect plotted with echoes colored by both substrate and relief.

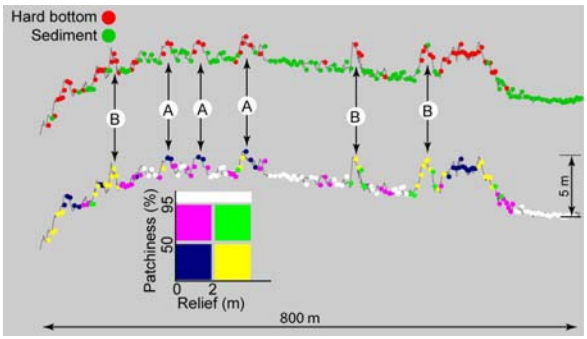

Figure 6: Cross shelf profile of part of the Navassa Island insular shelf. Top: Echoes colored by substrate only, red for hard bottom and green for sediment. Bottom: The same transect with echoes colored by a combination of local patchiness and relief. Patch reefs marked A and B were low and high relief, respectively.

Two types of patch reefs are highlighted along the transect (Fig. 6). Reefs labeled "A" and "B" had similar cross-shelf width, but those labeled "B" had higher relief. Considering substrate only, these reefs were all the same class (hard bottom), but considering both patchiness and relief, the low and high relief patch reef categories were objectively discriminated (yellow vs. blue class).

Franklin et al. (2003) produced a habitat map of the Dry Tortugas using a classification scheme based on patchiness and relief, but the map was based on

qualitative interpretation. The advantage of using a single-beam acoustic approach, as described above, for this type of classification is that it is objective and automated.

Conclusions

The results of this study showed that the QTCV commercial single-beam acoustic seabed classification system discriminated rocky from sediment substrate with about 80% accuracy. This result was confirmed with surveys at multiple sites using the same QTCV system and different methods for ground truth.

Two examples were given demonstrating that even a simple rock/sediment classification can improve habitat mapping of coral reefs. One example showed that using substrate information improved an interpretation of fish habitat based on bathymetry alone. The second example showed that QTCV single-beam data were capable of objectively classifying habitat based on patchiness and relief, whereas previous efforts to do so had relied on subjective analyst interpretation.

Due to the robust capability to extract bathymetry and basic rock/sediment substrate classification, combined with low cost and portability, single-beam systems have the potential to complement other survey methods in coral reef mapping efforts.

Abstract. To adequately image through a water column and delineate variation in coral reef ecosystem benthic cover types, sensors having high spatial resolution, high spectral resolution and high signal-to-noise are needed. Further, there is a need to better understand the optical properties of coral reefs, seagrass, other benthic cover types, and water column constituents from field-collected data so current and future remote sensing can be optimized for coastal zone ecosystem research and management. In August 2004, we flew the Airborne Visible Infrared Imaging Spectrometer (AVIRIS) and Cirrus digital camera system (DCS) on a NASA ER-2 over Puerto Rico. Also, in December 2005, we flew AVIRIS on a Twin Otter over priority sites for Puerto Rico for assessment of the 2005 Caribbean coral reef bleaching event. For each of these deployments, we collected coincident spectral data from dominant bottom types and coral under various health conditions using a hand-held spectroradiometer. These spectral data are being used to classify different benthic cover types present within the AVIRIS imagery. An overview of the airborne missions and coincident field data collection for calibration and validation of the airborne remote sensing data are presented along with preliminary image and field-collected spectral data products.

Key words: Coral reefs, hyperspectral, AVIRIS, airborne remote sensing.

Introduction

The photosynthetic pigments in the symbiotic algae (zooxanthellae) of corals and the general establishment of corals in shallow well-lit waters enables the detection of spectral information from corals through a clear shallow water column with a remote sensing instrument. Corals display distinct reflectance features between 550 and 650 nm related to the densities of chlorophyll-*a* and accessory pigments in their tissue (Holdren and LeDrew 1998; Myers et al. 1999; Hochberg and Atkinson 2000; Hochberg et al. 2003). Research has shown that spectral distinction of reef bottom types (i.e., coral, algae, and carbonate sand) is possible using field spectroscopy (Clark et al. 2000; Hochberg and Atkinson 2000; Andrefouet et al. 2001; Lubin et al. 2001; Hochberg et al. 2003; Wettle et al. 2003). Of further interest is the identification of spectral features indicative of degradation in reefs which could lead to better ecological assessment (e.g., relative health and biodiversity) and forecasting (Call et al. 2003; Hochberg et al. 2003).

Because only the visible range of the electromagnetic spectrum can penetrate deep enough into the water column to reach shallow-water benthic cover types, there is a unique requirement for not only high spatial- but high spectral-resolution remote sensing data to adequately discriminate benthic cover types, variations due to disturbance, and changes in reef ecosystems in an optically complex environment. Recently, remote sensing of coral reef communities has evolved from purely multispectral (e.g., Landsat) to improved mapping using higher spatial resolution multispectral (e.g., Ikonos) (Mumby and Edwards 2002; Purkis, 2005) to advanced hyperspectral (e.g., AVIRIS) techniques (Goodman and Ustin 2007).

Hyperspectral sensors provide a greater range of fidelity when discriminating between bottom types, because details of spectral shape and pattern are better revealed using numerous narrow bands rather than fewer broad multispectral bands (Holden and LeDrew 1999; Zimmerman and Wittlinger 2000; Butler and Hopkins 1970). As the water depth increases, light in longer wavelengths (>600 nm) is attenuated more readily than in green to blue wavelengths (shorter wavelengths), leaving only blue and green wavelengths (400-600 nm) with which to differentiate corals and other substrates (Green et al. 2000; Holden and LeDrew 2002). We are leveraging the high number of channels and narrow bandwidths of NASA's airborne hyperspectral remote sensor, AVIRIS, to provide a more comprehensive

assessment and mapping of shallow coastal resources (Guild et al. 2007).

The objectives of the coincident AVIRIS and field data collection missions included 1) mapping coral reef benthic type and degradation and 2) interpretation of reef biodiversity and variability.

Materials and Methods

Study Site. Our field site is the La Parguera shelf, southwestern Puerto Rico (17º 57' N, 67º 02' W: Fig. 1). La Parguera has numerous bank reefs that protect the shore from intense wave action, resulting in extensive seagrass meadows and a coastline dominated by mangroves with algal plains, sandy lagoons and two bioluminescent bays. This area has minimal input of suspended sediments or dissolved organic matter from land sources due to low precipitation and absence of riverine input. Annual precipitation ranges from 500 to 1,200 mm with a dry period from December through April.

Figure 1: The study site, designated by a star, is La Parguera in Southwestern Puerto Rico. This AVIRIS image was acquired during the 2004 AVIRIS mission. This RGB composite image displays channels 31, 21, and 10 at wavelengths of 655, 559, and 453 nm, respectively.

Airborne Missions. On August 19, 2004, AVIRIS and DCS were flown along the majority of coastal Puerto Rico, including Vieques Island to the east. The altitude of the NASA ER-2 was approximately 20 km, resulting in 17 m AVIRIS pixel resolution and 7 m DCS pixel resolution.

In mid-December 2005, in response to the most devastating regional-scale coral bleaching event on record in the Caribbean (Wilkinson and Souter 2008), AVIRIS/DCS was again flown over sites in Puerto Rico, as well as the US Virgin Islands, to investigate areas of coral bleaching. AVIRIS and DCS were flown onboard the NASA Twin Otter platform at an altitude of approximately 3.5 km for sensor spatial resolutions of 3.5 m and 0.7 m, respectively. Further, an additional DCS camera was flown on a low-altitude aircraft the week following the AVIRIS mission in Puerto Rico acquiring 15 and 30 cm spatial resolution data at 1 and 2 km altitudes, respectively.

AVIRIS has 224 contiguous spectral channels with wavelengths from 380 to 2500 nm and a 10 nm nominal bandwidth. AVIRIS has a high signal-to-noise ratio and has 32 channels in the visible wavelength range (400-700 nm), which are valuable for use in shallow water environments. The signal-to-noise ratio varies by wavelength from about 1000 in the visible region to about 500 in the infrared region and also exhibits reduced signal-to-noise in atmospheric absorption wells (e.g., water vapor) in bands located at or very close to wavelengths where atmospheric absorption appears (e.g., reduced reflectance in AVIRIS bands 62-64 corresponding to 929.0, 945.1, and 954.5 nm due to water vapor absorption around 945 nm).

The Cirrus DCS is a high resolution, medium format, color-infrared digital camera. The camera uses a Zeiss lens and provides 16-megapixel resolution. The camera can operate in visible (natural color) or color infrared mode. Visible mode (e.g., red, green, blue channels only) was used for our deployments.

In Situ Measurements. Underwater field sampling of four patch reefs across La Parguera shelf and surface measurements were conducted during both airborne deployments to support the classification of AVIRIS imagery based on benthic type, and for validation of AVIRIS atmospheric and sunglint correction schemes. A summary of the measurements are as follows: *in situ* reflectance (R) of corals and other benthic communities, spectral water attenuation coefficients (K_d), chlorophyll, turbidity, surface remote sensing reflectance (R_{rs}) for calibration, and sunphotometer measurements of aerosol optical thickness (AOT) for atmospheric correction.

For water column characterization and correction of reflectance data, we use Hydrolight (Sequoia Scientific) radiative transfer algorithms. Water column light attenuation coefficients (K_d) were calculated from the average of three to five spectra of a spectralon panel at three depths using a GER 1500 (Spectra Vista Corp.) handheld spectroradiometer in an underwater housing. These K_d estimates serve as an independent verification of the range of appropriate K_d values used for Hydrolight. Only two depths are necessary for the calculation, but extra K_ds were collected to avoid sensor saturated data from wave focused light effects on the spectralon.

Spectra from bright and dark validation targets (10 m x 10 m) were measured with the GER 1500 during the 2005 overflights. Aerosol optical depths (AOT) were measured using two Microtops sunphotometers (Solar Light Co., Inc.) with calibrated filters for aerosols and ozone, both operated onboard

boats at the patch reef study sites during the 2004 and 2005 overflights. These AOT estimates provide independent estimates for evaluating the range of appropriate AOT values used for the atmospheric correction algorithm (Lobitz et al. 2009; these proceedings).

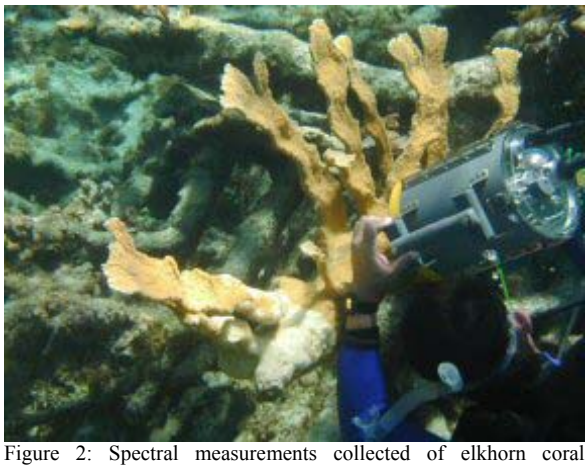

Figure 2: Spectral measurements collected of elkhorn coral (*Acropora palmata*) using the GER 1500 spectroradiometer in underwater housing.

Spectral measurements of dominant benthic cover types (including ecological variation) along 10 m transects were collected at each reef site for calculation of reflectance of benthic types and for spectral library input into classification algorithms for delineation of benthic cover types and for evaluation of variability within and between benthic cover types. The distribution of these transects were randomly placed and stratified to represent example coral stands in forereef, reef crest, and back reef areas. The linear transects were positioned to sample an extent of a reef patch that was mostly homogeneous and would dominate even a 17 m AVIRIS pixel. Three to five spectra were taken each for the spectralon and benthic type (Fig. 2) at 1 m intervals on both sides of the metric tape along each 10 m transect. GPS positions were recorded at the transect endpoints and dGPS positions were established at a later date. Further, additional spectral library measurements and GPS positions of other dominant bottom types were taken around the transect tape to use in image classification. A photo record was taken of each GER spectral reading. The perimeters of several large coral stands were also recorded as polygons of GPS points to train/validate benthic classification.

Image Processing. We are employing new approaches for hyperspectral data analysis to study coral reef biology and optical properties and to evaluate the inherent spectral heterogeneity of cover types within pixels (Goodman 2004; Goodman and Ustin 2007; Roberts et al. 1998). *In situ* spectral libraries, collected specifically from sites in the study area, are being used in spectral mixture analysis algorithms for subpixel benthic classification and the assessment of changes in reef composition, particularly biodiversity.

Raw AVIRIS data are being processed utilizing a sequence of image processing steps to resolve the complex interaction of atmospheric conditions, bathymetry, sea surface state, water optical properties and bottom composition (Fig. 3).

The analysis starts with three phases of image preprocessing, which includes stray light suppression, atmospheric correction and sun glint removal, and then image processing utilizes a semi-analytical optimization model to retrieve bathymetry and water properties throughout the study area. Using field spectra data representing the dominant benthic components (e.g., spectral endmembers for sand, coral, and algae), a constrained non-linear unmixing model is utilized to classify the benthic substrate as a function of the fractional contribution from each endmember. The final step utilizes field observations to assess the accuracy of the resulting image products.

Preprocessing. The first step of the image preprocessing is suppression of the near-infrared glow (i.e., anomalously large values) in low-light AVIRIS 2004 and 2005 imagery. This glow was caused by stray-light leakage following an upgrade to the instrument prior to the 2004 flight season. It is suppressed by calculating a correction based on the glow's cross track profile and the difference between the central stripe of "good" data and the adjacent incorrect pixel values that include the contribution from the stray-light. Details of the stray light suppression can be found in Lobitz et al. (2009; these proceedings).

The second preprocessing step is atmospheric correction, performed using Tafkaa, an algorithm for atmospheric correction of imaging spectrometry data under development at the Naval Research Laboratory designed to address the confounding variables associated with shallow aquatic applications (Gao et al. 2000; Montes et al. 2003; Montes et al. 2001). The Tafkaa algorithm includes atmospheric gaseous absorption and aerosol corrections as well as pixel location-specific solar and viewing geometry to retrieve per-pixel water surface reflectance. Details of the atmospheric correction methods can be found in Lobitz et al. (2009; these proceedings).

The third preprocessing step, a spectral normalizing procedure based on Hedley et al.'s (2005) variation of Hochberg et al.'s (2003) method was used to reduce the effects of sun glint (i.e., specular reflection from the water surface). In this method the slope of the regression line between pixel values from a NIR-band (750 nm) and each of the visible bands is

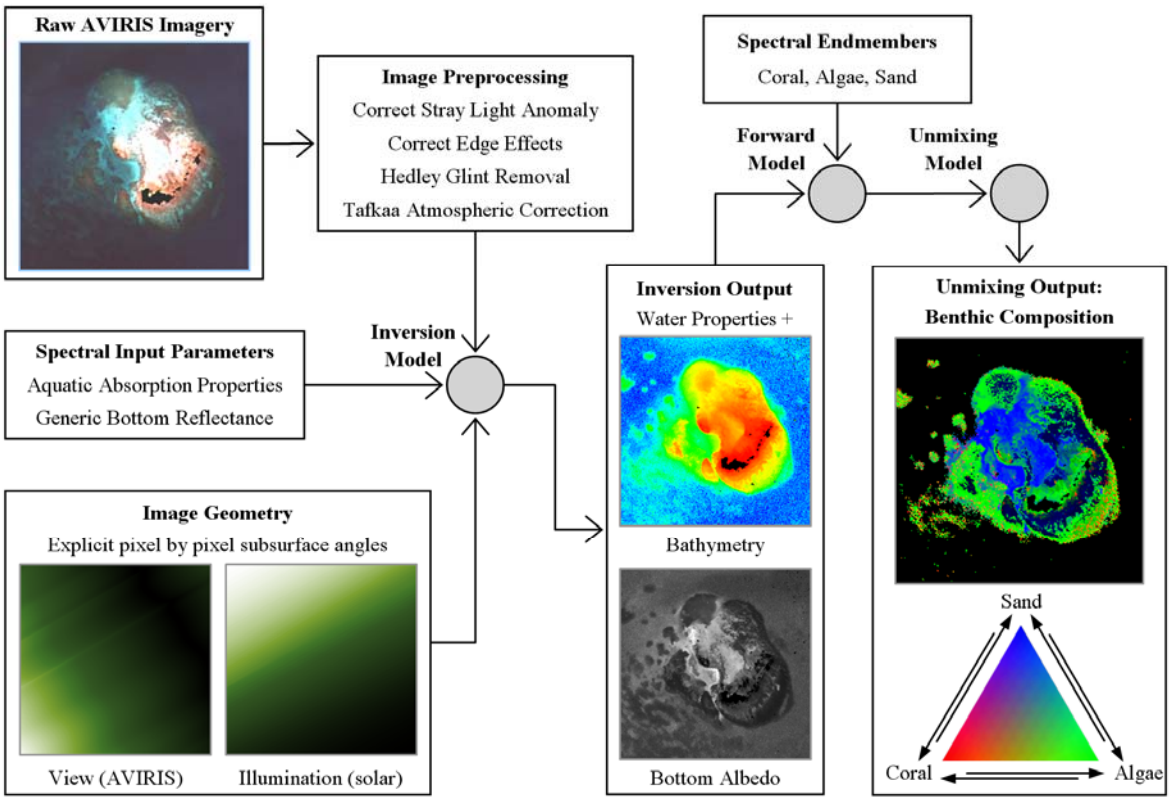

Figure 3: Overview of AVIRIS processing steps. On the left side are the inversion model processing inputs (corrected AVIRIS, spectral input parameters, and image geometry) and outputs (water properties, bathymetry, and bottom albedo) using a subset of the AVIRIS data for San Cristobal patch reef. On the right side are the forward model inputs (spectral endmembers, inversion output, spectral input parameters, and image geometry), integrated with the preprocessed AVIRIS imagery in the unmixing model to produce the benthic composition (sand, coral, and algae)

computed over a sample containing sun glint. This slope is then used to reduce the values in each visible band, relative to the difference between the NIR-band minimum value within the training area and the location-specific NIR-band value.

Inversion Model and Unmixing. Following image preprocessing corrections, a semi-analytical inversion model is used to retrieve estimates of bathymetry and water properties from measured surface remote sensing reflectance to correct for water column effects in the imagery (Fig. 3). Aquatic absorption properties are a combination of absorption properties of pure water and empirical spectra derived from field data and Hydrolight runs (Lee et al. 1998; 1999). The generic bottom reflectance used in the model is an average sand spectrum from the study area. Image geometry data indicate calculated variations in view and illumination angles within the AVIRIS image (Fig. 3). The Inversion Model is applied to derive water properties, bathymetry, and bottom albedo.

We then proceeded with defining spectral endmembers from measured field data and performed the benthic classification using unmixing techniques (Fig. 3) (Goodman and Ustin 2007; Goodman 2004).

Generic spectral endmembers of coral, sand, and algae (including a shade endmember) are used together with the inversion model outputs (water properties, bathymetry, bottom albedo) as well as the spectral input parameters and image geometry in the Forward Model. The next step is to take this information and run the Unmixing Model on the AVIRIS data to output a benthic composition image of coral, sand, and algae.

Results

The output benthic composition shows a predominance of algae and sand. The prevalence of algae in the reef areas is reasonable due to the pervasiveness of reef stands of rubble overgrown with algae. Since we have not delineated spectra for seagrass, seagrass in the back reef zone is classified as algae. We are currently evaluating the preliminary benthic composition image product and rerunning the unmixing model with additional spectral endmembers (including seagrass) to evaluate variation in the benthic composition output image (Fig. 3). The next step is to utilize field observations and DCS imagery to assess the accuracy of the resulting image products.

Discussion

Our research strategy includes refining the classification and evaluating our spectral transects with multiple endmember spectral unmixing as an additional approach to benthic classification.

A rich data set from the AVIRIS airborne and field deployments provide a unique opportunity to advance studies in changes in coral reef ecological structure and biodiversity. The magnitude of field studies ongoing in our study sites, as well as data collected specifically to support the airborne deployments, provide a strong baseline of information for thorough analysis of the reef ecology and biodiversity in these regions. The lessons learned about which spatial resolutions are most appropriate for sensing coral reef benthic communities will provide specification requirements for future hyperspectral sensors onboard conventional aircraft, unmanned aircraft systems (UASs), and spaceborne platforms.

An investigation of seagrass patterns at Alphonse Atoll, Seychelles: Linking structure to function in marine landscapes

S. Hamylton[1] and T. Spencer[1]

1) Cambridge Coastal Research Unit, Department of Geography, University of Cambridge, Downing Place, Cambridge, CB2 3EN, UK

ABSTRACT: The idea of landscapes as shifting patch mosaics, structured by a range of biological and physical stochastic forces, is well suited to shallow tropical environments, where seagrass patches lie within a matrix of soft sediments or rocky substrates. The interaction of wave fields and tidal currents with carbonate sediment transport can result in linear morphologies of reef flat material with alternating sand tongues and seagrass beds. Patch-level metrics capture phenomena such as linearity in one variable, which can be evaluated over a gradient of predictable environmental change. Interrogating the statistical properties of patch ensembles enables the links between observed structures and the processes that govern them to be empirically investigated. This study demonstrates how habitat maps derived from remotely sensed Compact Airborne Spectrographic Imager (CASI) data can be used to investigate critical controls of landscape mosaics through the application of geostatistical techniques to Alphonse Atoll, Seychelles.

Key words: Landscape ecology, patch linearity, remote sensing

Landscape ecology is characterised by the empirical investigation of the structure and function of land surface features (Forman and Godron 1986), with particular regard to spatial heterogeneity on biotic and abiotic processes (Risser et al. 1984). The broad scale of a landscape implies that internal processes can be observed across a spectrum of spatial scales, by dividing landscapes into patches, providing a tool for the representation of reality that can be readily understood. Patch-level metrics capture a feature of interest in one variable, which can then be evaluated over a gradient of predictable environmental change. In this way, ecologists are able to quantify and empirically link structure and function at the landscape scale.

Four key requirements for seagrasses are a marine environment, adequate rooting substrate, sufficient immersion in seawater and illumination to maintain growth (Hemminga and Duarte 2000). Seagrass landscapes are composed of seagrasses (marine angiosperms) and unvegetated sediments. Studies of seagrass dynamics at the landscape scale have generally focused on mapping historical change in distribution and cover over time, doing little to link observed structures to underlying processes driving change. Across a gradient of increasing hydrodynamic activity, seagrass beds form patterns that range from continuous meadows to widely dispersed, discrete patches (Fonseca and Bell 1998).

Terrestrial landscape ecologists have developed paradigms on island biogeography and fragmentation that have not crossed over to marine landscapes, which have traditionally focused on patch dynamics (Fonseca and Bell 2006). Sub-littoral landscapes are often viewed as a shifting biological mosaic of multistate systems structured by competition, grazing and predation. Such a viewpoint argues for a shift in focus, from the individual patch to the statistical properties of the entire ensemble. Landscape ecology techniques have emerged as a useful means of investigating functional drivers, such as the influence of wave exposure on community composition (Turner et al. 1999) and the relative influence of internal and external drivers (Fonseca et al. 2008).

Location

Alphonse Atoll (Figure 1) lies at the southern end of the Amirante ridge on the southwestern margin of the Seychelles Plateau, western Indian Ocean. The atoll covers an area of approximately 6x4km and consists of a narrow fore-reef shelf, wide peripheral reef flats and a dish-like lagoon reaching depths of 10m (Spencer et al. 2000). Alphonse is subject to a semi-diurnal tidal regime of range ~2m, upon which reversing monsoons control the direction and strength

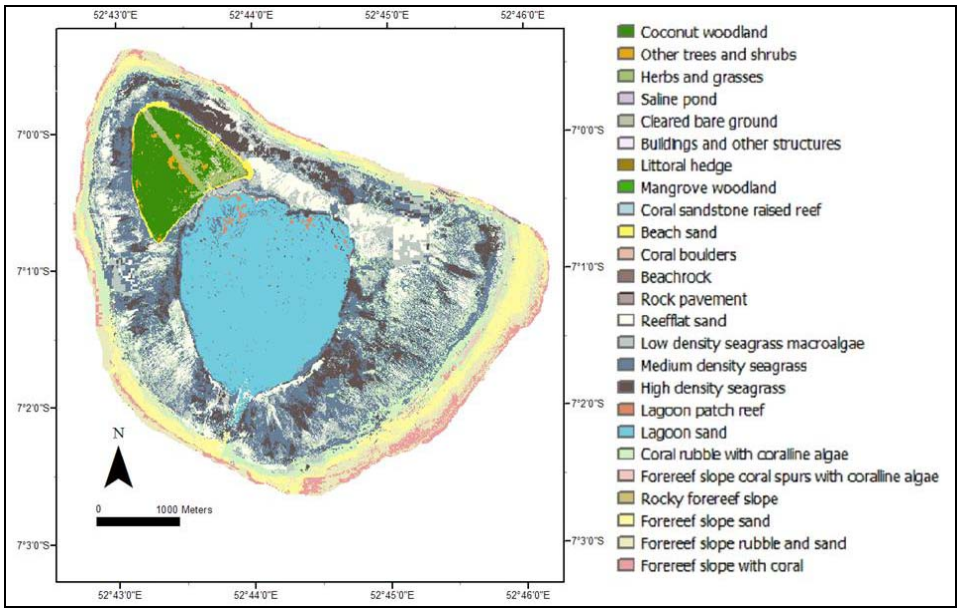

Figure 1. A habitat map of Alphonse Atoll, Southern Seychelles, West Indian Ocean (7°S, 52°E).

of surface currents. However, for the majority of the year, Southeast Trade winds dominate incident wave activity. The upper fore-reef exhibits distinct coral spur and groove formations. These extend around the atoll perimeter, being particularly well developed on the south-east and north-western windward coastlines. A distinctive feature of the adjacent reef flat is alternating linear tongues of seagrass on carbonate sediments. Similar features can be observed on many Indian Ocean reef flats and the aim of this paper is to investigate the functional role of spur and groove morphology, along with wave power, as drivers of these linear seagrass structures on the reef flat

Methods

A habitat map was generated from remotely sensed data acquired with an aircraft-mounted Compact Airborne Spectrographic Imager (CASI). Seventeen spectral bands of data were acquired at a spatial resolution of 1 sq.m, yielding synoptic coverage of the area of interest. Following geocorrection, flight strips were mosaiced using a band-wise linear colour balancing model to minimise across-track variance, with histogram matching to adjust for radiance offsets. Image bands were corrected for the effects of light absorption and scattering in the water by approximating the vertical radiative transfer through a water column to a logarithmic decrease with increasing depth (Lyzenga 1981). Training areas derived radiance measures over a number of spectral subclasses to build up statistical populations of habitat classes apparent in the image feature space. A maximum likelihood classification was performed on depth invariant bands, assigning each pixel of the image to the most likely habitat class on the basis of statistical probability. Map accuracy was assessed by exporting 283 polygon centroid coordinates to a hand-held GPS and comparing the corresponding location in the field to the habitat type recorded on the map. Overall accuracy was defined as the total number of correct patches divided by the total number of patches in the validation assessment.

Field data were collected on spur and groove depths and wave power was empirically modelled to derive information on potential drivers of seagrass patch structure as a response variable. Gustafson and Parker (1992) developed a metric for assessing patch linearity based on the premise that elongated patches of a given area are comprised of pixels closer to their edges than square patches of the same area:

$$LINEAR = \frac{\left[\frac{a_{ij}^{*}}{(2b-r)^2}\right] - 1}{a_{ij}^{*}} \qquad \textit{Equation 1.}$$

where a_{ij}^{*} =area of patch ij in terms of number of cells, and b = average cell value of the pixels comprising the patch. r = 0 if the patch contains side by-side pixel rows; 1 if not.

Six analysis windows were established in the centre of the reef flat to investigate seagrass community structure around the atoll. Linearity was calculated step-wise for each patch by calculating Euclidean distance from patch boundaries and averaging pixel values across patch spatial extents. A focal rank operator was used to record the number of pixels in

the immediate neighbourhood with a value less than the centre pixel. For each pixel of the input distance surface local maxima were returned as zero values in an output thematic layer. An optimal sample window size was defined using an experimental semivariogram. This was calculated by sequentially comparing the linearity of each individual patch to the rest of the patches in the map via the Moran statistic and plotting these values against the distance between patches. The lag distance at which the maximum semivariance was reached for linearity of all seagrass patches within the landscape was found to be 300m; hence this was adopted as the sample window dimensions.

Field measurements of groove depths were made using a Norcross DF2200PX handheld bathymetric sounder. A 50m transect was established along a defined bearing, along which a diver swam at a constant depth above the spur and groove morphology, perpendicular to the direction of groove alignment. GPS locations were recorded at both ends of the transect and depth measurements were recorded at 1m intervals.

Wave power was calculated using an amended version of the approach described by Roberts (1974). Transects of 5km length were established across the atoll cross section, running towards the lagoon centre, at ten degree intervals around the atoll. A bathymetric map facilitated derivation of a shoaling coefficient for each pixel for a given depth to wavelength ratio. Additionally, a refraction coefficient was calculated from the change in angles between the waves and shoreline and wave velocity (Weigel 1964). Mean wave height and period were hindcast for the outer point of each transect using data on wind strength, frequency and fetch taken from the Indian Ocean volume of the *Marine Climatic Atlas of the World* (US Navy 1958). Wave height was then computed for each pixel along the transect as a function of the wave height at the previous interval, change in shoaling coefficient, and change in refraction coefficient.

The influence of water movement was investigated on seagrass structure by carrying out regressions of patch linearity against independent variables at two spatial scales. In the first instance, descriptive bivariate regressions were used to explore the separate influence of "groove depth" and "wave power" on the linearity of patch assemblages within analysis windows. Geographical variation in the residuals of these bivariate models was reviewed to investigate additional model covariates. Multivariate regression was used inferentially to extend statements about the mean patch statistics from sample windows to the patches comprising the rest of the atoll habitat map. Tests were run to ensure the assumptions of multiple regression were met.

Results

Figure 2 summarises the geographical distribution of the information collected. Key points to note include:

-A good quality image classification was achieved, providing a clear and accurate representation of the heterogeneity apparent in the raw image (overall accuracy = 77%)

-Upper terrace spur and groove adjacent to the survey windows was well pronounced on the southeast and northwest faces of the atoll, where deep grooves were prevalent (Fig. 2).

-Lower relief spur and groove was recorded adjacent to the remaining sites, where wider, less frequent spurs divided shallower grooves.

-The wave power model indicated that the southeast-facing coastline of the atoll was subject to higher energy levels than the remainder of the atoll

-Computed values for the linearity metric (Equation 1) ranged between 0.22 and 0.67 for seagrass patches on the reef flat.

Bivariate regressions of groove depth and wave power with linearity values for seagrass patches falling inside adjacent survey sites on the reef flat revealed moderate positive correlations (Table 1). This suggested that the better "developed" the spur and groove morphology, the more linear the adjacent seagrass patches.

Descriptive bivariate regressions: Functional characteristic Vs Linearity	**R^2**
Average groove depth v Linearity	0.581
Average wave power v Linearity	0. 431
Multicolinearity check	
Average groove depth v Average wave power	0.397
Inferential multivariate regression	
Groove depth and wave power v linearity	0.813

Table 1. Diagnostics for the descriptive bivariate and inferential multivariate regressions of seagrass linearity against groove depth and wave power, individually and collectively.

The groove depth and linearity bilinear regression gave rise to positive residuals on the west side of the atoll and negative residuals on the east side, approaching unity in the southeast. Comparison of the groove depth and wave power model revealed both variables to be at a maximum on the southeast region of the atoll. The east side is subject to high energy levels relative to shallow groove depth, whereas the west side has deeper grooves and lower energy in relative terms. The combined influence of adjacent groove depths and incident wave power explained 81% of the variation in seagrass patch linearity across the overall habitat map.

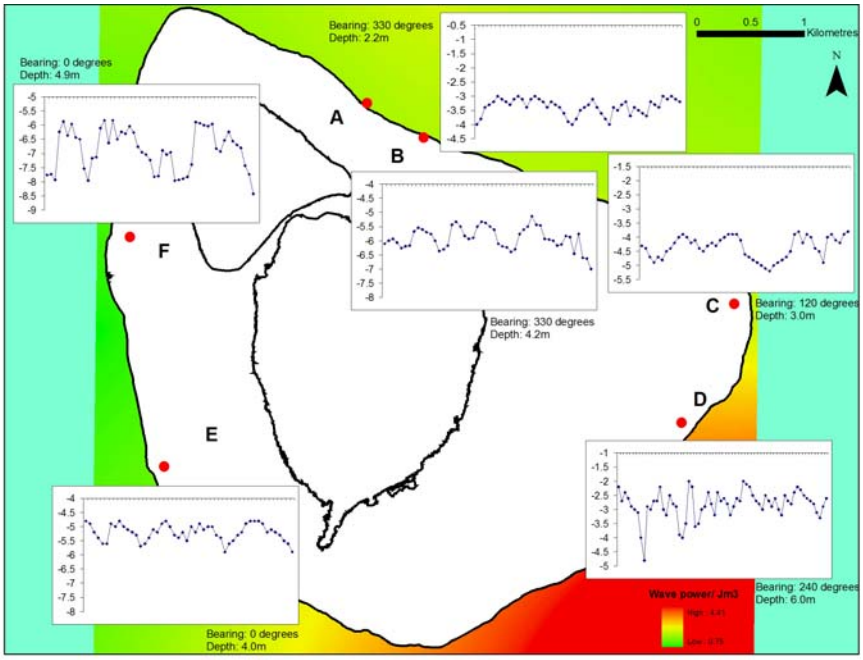

Figure 2. Analysis sites at Alphonse. Profiles of adjacent spur and groove, superimposed onto the wave power model. Each spur and groove profile represents a 50m transect across the given depth and bearing. Incident wave power ranges from 4.41-0.75Watts per cubic metre.

The estimated regression function reads:

$$\textit{Patch linearity} = -0.234 + 2.584\times10^{-3*}\textit{wind factor} + 3.93\times10^{-3*}\textit{groove depth}$$

T-test values were 9.337 and 12.429 for the mean wind force and groove depth respectively (561 degrees of freedom; $p<0.001$), suggesting it to be highly likely that the estimated coefficients are different from zero. Diagnostics indicated compliance with the assumptions of multiple regression.

Discussion

In general, seagrass patches on the reef flat are more linear than the overall habitat mosaic at Alphonse (0.2). Linear morphologies are likely a patch scale response to the hydrodynamic setting on the reef flat; such bed forms have been observed for *Posidonia australis* (Cambridge 1975), *Cymodocea nodosa* (Marbà and Duarte 1994) and *Zostera marina* (Fonseca and Bell 1998). Alternate dark and white stripes were also noted on aerial photographs of Mayotte Barrier Reef (Guilcher et al. 1965). This is in accordance with descriptions of shallow seagrass beds on Indian Ocean reef flats as "stripey zigzag" patterns (Den Hartog 1971).

Given these linkages, the spatial pattern of linearity among seagrass patches can be linked to the absolute amount of energy reaching the coastline as a result of wind-driven surface waves, as confirmed by the bivariate regression (R^2=0.43). The plan-view pattern is one of abundant alternating linear patches of seagrass and sand in the Southeast and Northwest of the atoll, with lower values in the Northeast. The amount of energy reaching a shore is influenced by water depth, which is controlled by wave-setup and tides. Setup, the rise in mean water level above the still-water elevation of the sea due to waves breaking, is a significant determinant of reef-top sediment transport (Komar 1976). Experimental results have found wave setup and flow to increase with increasing off-reef wave height and period, and with decreasing reef top water depth (Gourlay 1996). Tides operate at a lower frequency and determine the geomorphic work that can be carried out on reef flats in two ways: through unidirectional currents with a diurnal tide frequency and by tides modulating reef flat wave energy through water level. At low tide, waves break on the reef edge and no significant energy is propagated across the reef top. However, at high tides, depth-limited waves are able to propagate across the reef-top. Such a distinction is important at Alphonse, where the ~2m tidal range coincides with the height of the reef crest.

Collectively, setup and tides separate out the influence of *(i)* wind-driven surface waves, and *(ii)* subsurface currents. This separation, along with the absence of multicolinearity between the explanatory variables of wave power and groove depth, justifies the inclusion of two functional drivers operating at different depths of the water column. The geographical distribution of residuals from the groove depth vs. linearity bilinear regression revealed spatial structure that suggested additional independent

variables to have been omitted from the model would have elevated values relative to groove depth on the east side of the atoll and lower relative values in the west, as was the case with wave power. The multivariate regression encompassed processes that differed in the nature of their influence on the independent variable, as evidenced by the greater level of explanatory power of the multivariate model.

The comparison of the distribution of patch linearity to adjacent spur and groove morphology may be explained by the transformation of energy from the outer to inner sections of the reef complex. Spurs contribute to energy dissipation through the action of bottom friction against subsurface currents on the upper terrace. Frictional attenuation over spurs lowers the energy available for particle entrainment, inducing deposition closer to the reef crest. In areas adjacent to grooves, lower lying topography and a smaller surface may promote extended entrainment, producing sand tongues that extend further onto the reef flat. An energy attenuation profile could therefore be established for landward-moving reef flat water that reflects the spur and groove topography further offshore.

Conclusion

Overall, it was found that spur and groove morphology (as measured by groove depth) and incident wave power had a moderate influence on reef flat seagrass patch linearity when treated independently, with greater explanatory power in a combined model.

The distinction between the two regression steps taken in this study highlights the importance of technique in landscape ecology studies. The bivariate regressions were "descriptive", in that they were carried out on patch assemblages inside analysis windows chosen to describe the apparent seagrass patterns as a representation of variation in a response variable where all covariates were not necessarily present in the model. Geographical variation in the residuals from this step was a useful basis for addition of a covariate that enhanced the explanatory power of the model and allowed the descriptive statement to be extended to the whole habitat map.

The transition from descriptive to inferential modelling highlights the importance of good representation of both structural and functional phenomena that are commonly the focus of landscape ecologists. This analysis of patches (as the fundamental unit of habitat maps produced from remote sensing data), using landscape ecology techniques demonstrates the suitability of these combined tools for the specification, development and testing of empirical models that link structure and function in marine landscapes.

A pan-sharpening method for satellite image-based coral reef monitoring with higher accuracy

H. Hanaizumi[1], M. Akiba[1], H. Yamano[2], T. Matsunaga[2]

Abstract. A pan-sharpening method for enhancing satellite imagery is proposed as the first step for building a relatively high accuracy and low cost approach for image-based analyses of coral reefs. To achieve this objective, a low spatial resolution multi-spectral image was first spatially resampled (increasing the number of pixels) and co-registered onto a higher resolution panchromatic image. Based on multiple regression analysis, brightness information of the resampled multi-spectral image was replaced with that of the panchromatic image so that all spectral density scatter-diagrams exhibit linear characteristics with slopes equal to one and *y*-intercepts equal to zero. The method was characterized by its simplicity and faithfulness in preserving spectral (i.e., color) information. Since the resampled multi-spectral pixels were independently modified by the densities of the panchromatic pixels, all information in the panchromatic image was transferred to the resulting pan-sharpened image, thus producing lossless pan-sharpening. As a demonstration, the method was applied to FORMOSAT-2 data acquired on 31 January 2007 at Ishigaki Island, Ryukyu Islands, Japan.

Key words: Lossless pan-sharpening, panchromatic, multi-spectral, spatial resolution.

Introduction

A method for observing global changes in coral reef status is required. Remote sensing is an effective tool to map and detect broad-scale changes of coral reefs. The effectiveness of the mapping and detection using remote sensing depends on the spatial resolution of the imagery, where higher spatial resolution generally result in higher accuracy (Mumby and Edwards 2002; Andréfouët et al. 2002, 2003; Yamano and Tamura 2004). However, high-resolution satellite images are typically costly to acquire and process, which often discourages their use.

One solution to the cost issue is to introduce a pan-sharpening method to transform coarser spatial resolution satellite images into higher spatial resolutions (Nishii et al. 1996; Liu 2000). This approach has the potential to provide high-spatial resolution data at a lower cost than the direct purchase of high resolution multi-spectral imagery. Pan-sharpening is a data fusion method whereby the spatial resolution of a multi-spectral image is improved by injecting information extracted from a higher resolution panchromatic band. There have been many algorithms proposed for this type of data fusion. Recently, a public contest for pan-sharpening algorithms was performed (Alparone et al. 2007). Eight algorithms were evaluated in this contest and the GLP-CBD (Aiazzi et al. 2002, 2006) and AWLP (Otazu et al. 2005) algorithms were ultimately ranked as the best. Both algorithms use multi-resolution analysis (MRA) to achieve spatial enhancement and were derived directly from the values measured by the sensor. The algorithms also use a normalization process when transforming the multi-spectral pixel values using the panchromatic information to avoid spectral distortion

For effective image analysis, pan-sharpening methods should preserve spectral information throughout the image, including both land and water areas, and reduce errors associated with noise such as breaking waves. Since complicated processing itself may cause unpredictable noise, the pan-sharpening process approach should also ideally be simple and predictable. We propose a simple pan-sharpening method based on a multiple regression analysis. In the method, original multi-spectral images are spatially resampled (increasing number of pixels) and then modified so that scatter diagrams between pan-sharpened image and the resampled original image for all spectral bands exhibit linear relationships with slopes equal to one and *y*-intercepts equal to zero.

Material and Methods

A set of FORMOSAT-2 (Liu 2006) images acquired on 31 January 2007 at Ishigaki Island, Ryukyuu-Islands, Japan were used to demonstrate the proposed

pan-sharpening method. FORMOSAT-2 provides a total of four visible-near infrared multi-spectral bands at 8 x 8 m^2 spatial resolution and a panchromatic band at 2 x 2 m^2 spatial resolution. The panchromatic band covers the same equivalent spectral range as the four visible-near infrared bands.

Pan-Sharpening Model

In the proposed method, pan-sharpening is accomplished by replacing brightness information estimated from the original lower resolution multi-spectral (MS) bands with values derived from the higher spatial resolution panchromatic band. This process is performed while preserving the spectral information for subsequent image classification and analysis. Figure 1 illustrates how pixels for a single original MS pixel correspond with the 16 PAN pixels, and the resulting 16 pan-sharpened MS pixels. As shown in Fig. 1, the spectral reflectance values of the original MS are written as r (red), g (green), b (blue) and n (near infrared), and the corresponding panchromatic reflectance values are P_1 .. P_{16}. We regard the pan-sharpening problem as calculating the values r_i^P, g_i^P, b_i^P, n_i^P (i = 1 .. 16) as a function of a brightness estimator y, which is formulated as

$$y = f(r, g, b, n, P_1, \cdots, P_{16}). \tag{1}$$

In an early formulation of this algorithm (Gillespie et al. 1987), y was calculated simply as

$$y = (r + g + b)/3. \tag{2}$$

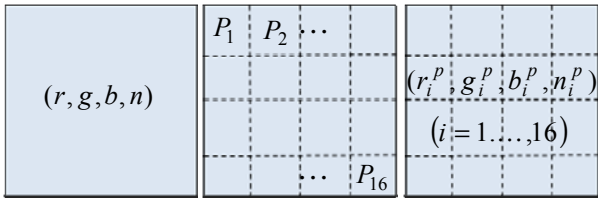

Figure 1: (a) Original MS pixel, (b) PAN pixels, and (c) pan-sharpened MS pixels.

Eq. (2) indicates that the brightness y is estimated by using just the lower resolution image, where the sum of r, g and b is a rough approximation of overall brightness. Liu used a more sophisticated function (Liu 2000) with y calculated as

$$y = \frac{1}{N}\sum_{i=1}^{N} P_i, \tag{3}$$

where N is the number of high resolution pixels corresponding to the lower resolution pixel. Liu's estimator was thus calculated using only the high resolution image. Once the estimator is obtained in the Gillespie et al. (1987) or Liu (2000) methods, the pan-sharpened values r_i^P, g_i^P, b_i^P, n_i^P (i = 1 .. 16) are calculated as

$$\left.\begin{aligned} r_i^p &= \frac{r}{y} P_i \\ g_i^p &= \frac{g}{y} P_i \\ b_i^p &= \frac{b}{y} P_i \end{aligned}\right\} (i = 1, \cdots, 16). \tag{4}$$

Since Liu's method is a form of a high pass filter, it works particularly well in photo interpretation. Both of the above methods, however, do not exactly preserve the spectral characteristics of the original multi-spectral image. This is evident when observing the scatter diagram of the original low resolution image and resulting pan-sharpened image does not have a linear relationship.

The proposed method is designed so that the pan-sharpened versus original density scatter diagram gives a perfectly linear relation with slope equal to one and a zero y-intercept. The method is a generalized algorithm that is equally applicable to both land and water applications. In this method we calculate the brightness estimator y as

$$y = a_0 r + a_1 g + a_2 b + a_3 n + a_4. \tag{5}$$

This model is derived from the fact that the panchromatic band covers the same spectral range as the visible (red, green, blue) and near infrared bands combined. Since the near infrared band reflectance is high in land (non-water) areas and almost zero in water areas, two separate versions of the model are utilized to independently represent the land and water areas respectively.

In the proposed method, each original multi-spectral pixel is first resampled into N pixels (N = 16 for FORMOSAT-2) so that resampled image has the same number of pixels as the panchromatic. All of the N pixels are initially assigned the same reflectance values as the original pixel

$$\left.\begin{aligned} r_i^e &= r \\ g_i^e &= g \\ b_i^e &= b \\ n_i^e &= n \end{aligned}\right\} (i = 1, \ldots, 16). \tag{6}$$

For the resampled image, Eq.(5) is rewritten as

$$y^e = a_0 r^e + a_1 g^e + a_2 b^e + a_3 n^e + a_4, \tag{7}$$

where y^e means brightness component of expanded pixel (i.e., resampled pixel). Using Eq.(7), the pan-sharpened reflectance values are calculated as

$$\left.\begin{aligned} r_j^p &= \frac{r_j^e}{y_j^e} P_j \\ g_j^p &= \frac{g_j^e}{y_j^e} P_j \\ b_j^p &= \frac{b_j^e}{y_j^e} P_j \end{aligned}\right\} (j = 1, \ldots, M), \qquad (8)$$

where M is the total number of pixels in the panchromatic image. Thus, the pan-sharpening problem is reduced to determining the coefficients a_0, a_1, a_2 and a_4 in Eq.(7). It is evident from Eq.(8) that when y_j^e equals to P_j the pan-sharpened pixel values are statistically the same as the original.

We use a multiple regression analysis to determine the coefficients as

$$P_j = a_0 r_j^e + a_1 g_j^e + a_2 b_j^e + a_3 n_j^e + a_4 \qquad (9)$$
$$(j = 1, \ldots, M).$$

Eq.(9) is rewritten as

$$\begin{bmatrix} P_1 \\ P_2 \\ \vdots \\ P_M \end{bmatrix} = \begin{bmatrix} r_1^e & g_1^e & b_1^e & n_1^e & 1 \\ r_2^e & g_2^e & b_2^e & n_2^e & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ r_M^e & g_M^e & b_M^e & n_M^e & 1 \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \\ a_4 \end{bmatrix}, \qquad (10)$$

or in matrix format as

$$\mathbf{P} = \mathbf{XA}. \qquad (11)$$

The coefficient vector **A** is obtained by using a generalized inverse solution

$$\mathbf{A} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{P}, \qquad (12)$$

where **X**‘ is the transpose matrix of **X** and $\mathbf{X}^{-1}$ is the inverse matrix of **X**. The pan-sharpened multi-spectral reflectance values are obtained by solving Eqs.(7), (8) and (12).

Spatial Co-Registration

The MS and PAN sensors on FORMOSAT-2 are physically separated, which produces a complex discrepancy in spatial registration between the two sensors. In order to remove this discrepancy, a spatial co-registration process (Hanaizumi et al. 1994) was applied to the FORMOSAT-2 imagery before implementing the pan-sharpening procedure. The co-registration process consisted of automated searching for common points in the MS and PAN bands, Delaunay triangulation using the identified points, and piece-wise affine transformation for removing the discrepancy and performing the co-registration. Since all of the MS bands are already co-registered, the co-registration process was simplified by first generating a single pseudo image by adding together the reflectance values from the individual *r*, *g*, *b* and *n* images. Analysis was then performed by co-registering the pseudo image with the PAN image. Approximately 1000 points were automatically identified as co-occurring in the pseudo and PAN images. Delaunay triangulation was used to generate a surface network from these points, and piece-wise affine transformation was then used to remove the discrepancy. In this approach, only the convex areas of the Delaunay triangulation were included in the co-registration process and subsequently utilized in the pan-sharpening model.

Results and discussion

The co-registration and pan-sharpening methods were applied to the FORMOSAT-2 imagery of the northern area of Ishigaki Island. The original imagery measured 4443 x 5359 pixels for the MS bands and 17321 x 19679 pixels in the PAN image. For the pan-sharpening model, all four MS bands (*r*,*g*,*b*,*n*) were used over land (non-water) and only the three visible bands (*r*,*g*,*b*) were used over water, which includes the coral reef areas of interest. Figure 2 shows the pan-sharpening results for a 3000 x 3000 pixel subset of the overall image.

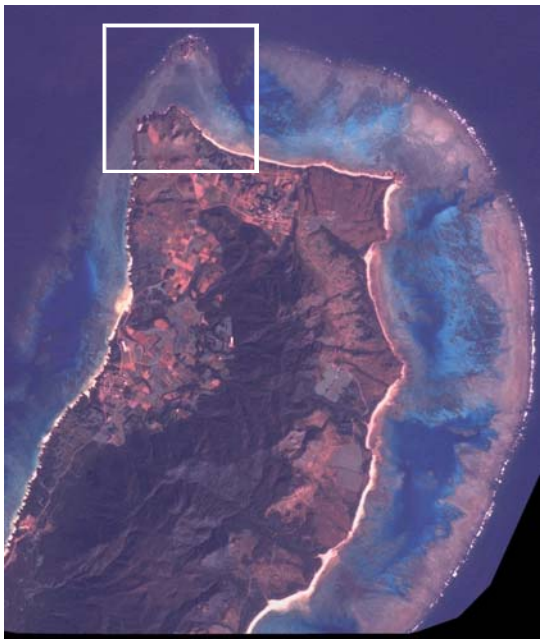

Figure 2: Pan-sharpening output for image subset, with focus area highlighted in white.

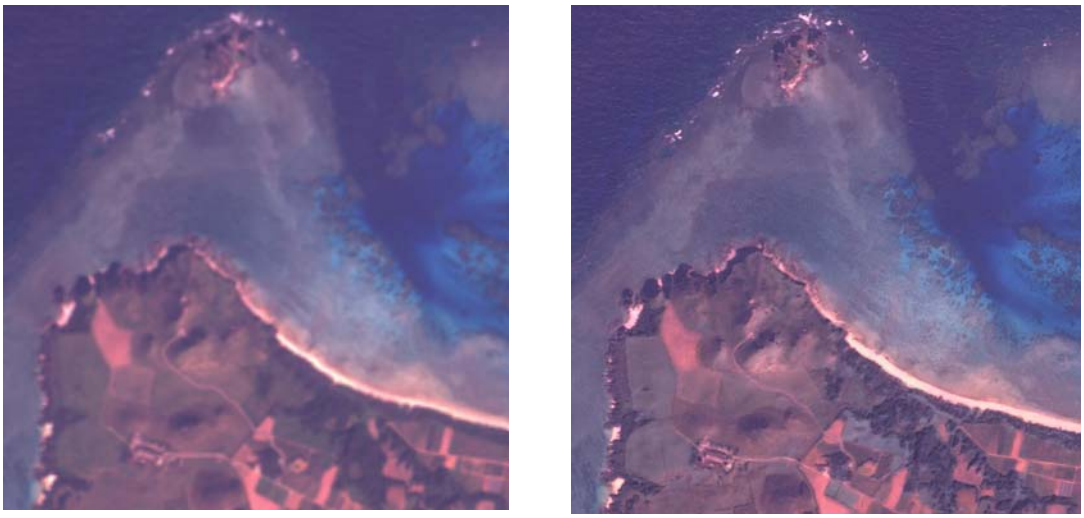
Figure 3 compares the pan-sharpening output with the original resampled image for the 800 x 800 pixel focus area indicated in Figure 2. It can be qualitatively observed that the pan-sharpened image preserves information from both the MS and PAN bands. This is because the pan-sharpening method modifies the MS pixel values using information from all bands.

In order to quantitatively evaluate the performance of the pan-sharpening model with respect to preserving spectral information, scatter diagrams were produced comparing the original resampled MS pixel values with the resulting pan-sharpened values. Ideally, this should be a linear 1:1 relationship, with a slope of one and a zero *y*-intercept. Figure 4 shows the reflectance scatter diagrams for the *r*, *g* and *b* spectral bands. In these diagrams, the *x*-axis indicates pixel values from the original MS image, and the *y*-axis is the pixel values after pan-sharpening. Further, the intensity (i.e., darkness) of each dot is proportional to the logarithmic frequency of pixels with that specific value. The red lines in these diagrams indicate the ideal 1:1 relationship. We can see that all scatter diagrams produce linear shapes closely approximating the 1:1 line. This indicates that the spectral information is preserved and that we have effectively obtained a higher spatial resolution color image of the coral reefs from the lower resolution original.

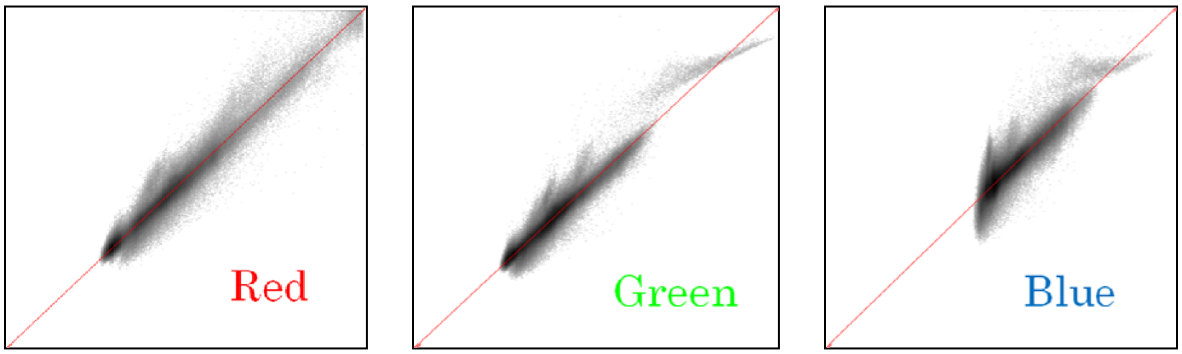
Conclusions

A pan-sharpening method was proposed which incorporates the panchromatic information without distorting the original spectral information. Application to coral reef imagery produced a visual improvement. The pan-sharpening was performed pixel-by-pixel, replacing brightness components of each lower spatial resolution MS band with higher spatial resolution values derived from the MS and PAN bands. It was also quantitatively shown that the resulting pan-sharpened image preserved the spectral (i.e., color) content of the original image. The multiple regression analysis used for this estimation is regarded as a type of density normalization between



(a) MS original color image. (b) Pan-sharpened image.

Figure 3: Comparison of pan-sharpening results with the resampled original image for a 800 x 800 pixel focus area.



(a) Red band. (b) Green band . (c) Blue band.

Figure 4: Density scatter diagrams between the pan-sharpened result (y-axis) and the original MS imgary (x-axis).

the multi-spectral bands and the panchromatic image. The model is applied over water using just the three visible MS bands, and over land using all four MS bands. By incorporating the higher resolution panchromatic information, the model also adds spatial information not present in the original lower resolution image.

The proposed method was successfully applied to FORMOSAT-2 data of Ishigaki Island, Japan. The spatial resolution of the MS bands was improved from 8 x 8 m to 2 x 2 m by implementing the pan-sharpening model. Spectral preservation performance was evaluated using scatter diagrams, which indicated results approximating the desired 1:1 relationship and thus confirmed effective performance of the model.

The authors next plan on using pan-sharpening method to monitor temporal changes in coral reefs using satellite remote sensing imagery. The development of appropriate change detection methods using this imagery is a subject of future study.

Abstract. Reef fish biodiversity is influenced by habitat, including such variables as coral cover, depth, rugosity, and the distance to the reef edge. Commercially available satellite imagery can be used to map these habitat variables, and fish biodiversity can be estimated using the resulting habitat maps. We present a case study from two reefs in Zanzibar, Tanzania, based on IKONOS imagery acquired concurrently with habitat and fish surveys. The influence of some habitat variables, difficult or impossible to measure in-situ but mappable using satellite imagery, such as habitat diversity and depth variability at a range of spatial scales, are also explored. We illustrate how well each habitat variable can be estimated using remote sensing, and how accurately a variety of models can predict the spatial distribution of reef fish biodiversity. High-resolution satellite imagery can map species richness with a Residual Standard Error of <5 species at the study site. Future refinement of habitat maps and of predictive models is expected to reduce prediction error.

Key words: Remote sensing, Habitat mapping, Reef fish biodiversity, Predictive models.

Introduction

The influence of habitat on reef fish diversity has been demonstrated in experimental and observational studies (Roberts and Ormond 1987; Friedlander and Parrish 1998; Gratwicke and Speight 2005). Habitat variables found to influence fish diversity typically include live coral cover (henceforth: coral cover), depth, rugosity, and habitat heterogeneity (Huston 1994; Chabanet et al. 1997; Jones et al. 2004). The predictive strength of these variables, individually or combined, has varied between studies (Jones and Syms 1998; Knudby et al. 2007). It is therefore prudent that any relationships be establish locally before they feed into management decisions, e.g. designation of 'high-diversity habitat' as protected.

We established habitat-fish relationships using in-situ data on a range of habitat and fish diversity variables, from two reefs in Zanzibar, one protected (Chumbe) and one un-protected (Bawe) (Fig. 1). We then assessed the feasibility of predicting spatial variation in fish diversity using remotely sensed estimations of the most important habitat variables.

Material and Methods

Three data sets were used for this study. Fish point counts were made at 93 sites on Chumbe and 51 sites on Bawe. Sites were located at a random number of fin kicks, in a random direction, from the previous site. Habitat data were also collected at these sites, as well as at 347 additional sites on Chumbe and 56 sites on Bawe, covering all major habitat types. IKONOS satellite data, from 2007 for Chumbe and 2005 for Bawe, covered both reefs.

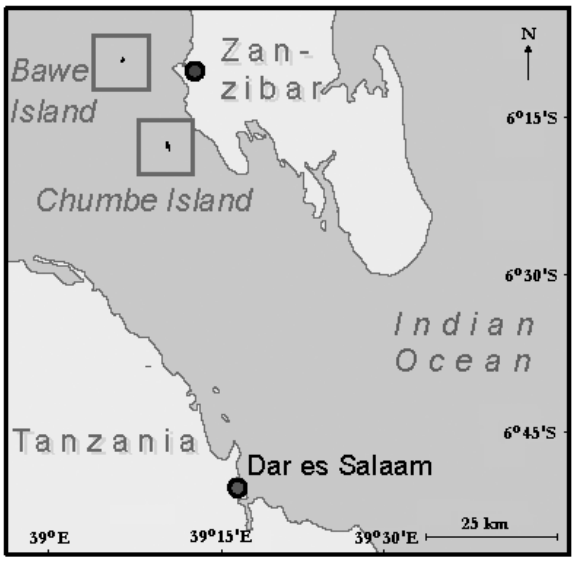

Figure 1: Study sites. The reef around Chumbe Island is effectively protected from direct human damage; the reef around Bawe Island is fished and used for dive and snorkel tourism.

Fish point counts

Fish point counts were carried out in 5m radius circles according to Bohnsack and Bannerot (1986). The location of each site was found by snorkeling in a random direction for a random number of fin-kicks from the previous site. Abundance and average length of all species were recorded.

Habitat surveys
For each site, maximum and minimum depth was measured with a dive computer, a GPS on a float was used for geolocation, coarse-scale rugosity (massive corals, patch reefs and low-frequency depth variation) and fine-scale rugosity (branching and digitate corals) were estimated on visual scales of 0-5 (Wilson et al. 2007), and substrate photos covering the 5m radius circle were processed in CPCe.

Satellite data
IKONOS images of the two reefs were preprocessed through geometric rectification, atmospheric correction with Atcor2, water column correction by calculation of Lyzenga's (1978) depth-invariant index, and sunglint removal (Hedley et al. 2005).

Data analysis
Fish point counts allowed calculation of three quantifications of the fish community: 1) species richness, 2) biomass, 3) Shannon-Weiner diversity. The biomass, based on length-weight conversion provided by FishBase (Froese and Pauly 2008), was used instead of abundance to mitigate bias in diversity calculations, otherwise caused by schools of *Chromis spp.*, often with several hundred individuals.

Depth measurements were used to calculate average depth and depth range (max depth–min depth). The substrate photos from each site were processed in CPCe (Kohler and Gill 2006) to extract percentage cover of substrate types. This also allowed calculation of coral cover, habitat diversity, and distinction between coral growth forms allowed calculation of the number of growth forms present at each site. The two reefs were processed independently.

From these sets of habitat and fish variables, individual correlations were explored. Ordinary least-squares (OLS) linear regression models were then developed to explain variation in each fish variable, and generalized additive models (GAM) were developed to account for non-linear relationships, and compared to OLS models using broken-stick transformed habitat variables. The Bayesian Information Criterion (Schwartz 1978) was used to include/exclude variables from both model types.

The satellite data were used to develop a number of products estimating habitat variables. First, a habitat map was developed, from which the habitat class and geomorphologic zone of each site could be derived. Classes were defined as: Dense coral (>40% cover), Sparse coral (5%-40% cover), Dense seagrass (>250g/m^2), Sparse seagrass (10-250g/m^2), Sand, Pavement, Algae, Deep Water (depth>15m). A linear regression of coral cover was derived from the depth-invariant index at each field site, and applied throughout the areas classified as coral in the habitat map, yielding a map of coral cover. Depth was estimated using the method by Stumpf et al. (2003), and rugosity was subsequently derived at a range of spatial scales (pixel sizes) using NOAA's Benthic Terrain Modeler with calculation from Jenness (2002). Finally the habitat map was used to derive a measure of habitat diversity at a range of spatial scales using NOAA's Diversity Calculator (Buja 2008).

Using only these remotely sensed habitat variables, new OLS and GAM models were derived, to assess the performance of IKONOS satellite imagery in predicting the fish variables.

Results
Correlations between fish variables and individual habitat variables showed several interesting patterns. Strong positive correlations with fish species richness on Chumbe were shown by both depth range (R=0.56) and coarse rugosity (R=0.66), presumably because they quantify the structural complexity of the reef at similar scales. Coral cover showed a similar correlation (R=0.58), as did the number of coral growth forms (R=0.55), with depth slightly less correlated (R=0.38). Similar results were obtained for Bawe, except for depth (R=-0.02).

Broken sticks
Analysis of the individual relationships showed that several were non-linear or piece-wise linear. Coral cover, depth, and coarse rugosity all showed positive (linear) correlations at low values, but reached a breakpoint after which further increase in the habitat variable did not lead to an increase in the fish variable.

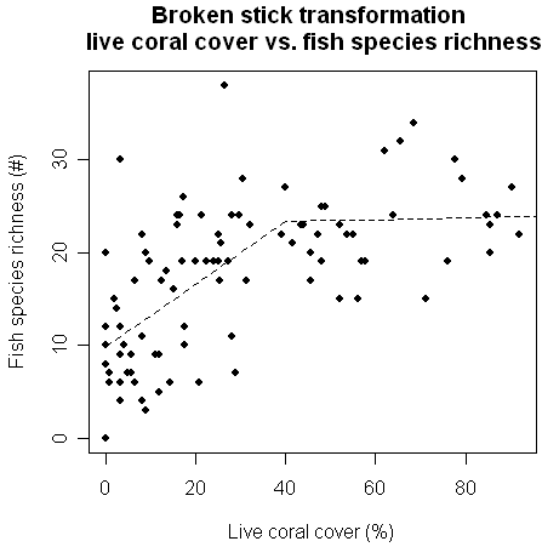

Figure 2: Broken stick transformation of the relationship between coral cover and fish species richness on Chumbe. The breakpoint at 40% coral cover was determined visually, but can be optimized to yield the best combined fit of the two segments.

Such a relationship is illustrated in Fig. 2, where additional coral cover beyond 40% doesn't lead to an increase in species richness (data from Chumbe).

When such relationships were evident, breakpoints were selected from a scatter plot, and broken stick transformations of the habitat variables were carried out. This improved individual correlation for depth range (R=0.71), coarse rugosity (R=0.73), coral cover (R=0.64) and depth (R=0.50). Variables showing linear relationships were not transformed.

In-situ model comparison

OLS models generally included variables with high individual correlations, with a few notable exceptions. Two OLS models for Chumbe included habitat diversity, which had low (non-significant) individual correlations with these variables (R=0.12 for species richness, R=0.15 for diversity). The model for biomass on Bawe included coral cover, but also three specific coral growth forms (digitate, massive and encrusting corals). All three had positive individual correlation coefficients, but negative coefficients in the OLS model. Model summaries, including GAM models and OLS models using the broken-stick transformed variables, are provided in Table 1. As expected, the GAM models produced the lowest residual standard errors (RSE) due to their flexibility.

Dependent fish variable	OLS	GAM	OLS BROKEN STICK
Chumbe: Adj. R^2 / Residual Standard Error			
Species richness (species)	0.550/5.42	0.651/**3.58**	0.648/4.79
Biomass ($g/100m^2$)	0.348/3354	0.453/**1963**	0.453/3070
Diversity (Shannon Index)	0.538/0.57	0.562/**0.38**	0.532/0.52
Bawe: Adj. R^2 / Residual Standard Error			
Species richness (species)	0.538/4.77	0.619/**3.27**	0.684/3.95
Biomass ($g/100m^2$)	0.472/995	0.621/**536**	0.507/962
Diversity (Shannon Index)	0.404/0.70	0.534/**0.47**	0.620/0.56

Table 1: OLS, GAM, and OLS broken stick models for Chumbe and Bawe. Lowest RSE values in **bold**.

Remote sensing of habitat variables

The remotely estimated habitat variables were limited to the following: coral cover, depth, rugosity, and habitat diversity.

Coral cover on Chumbe was estimated on a per-pixel basis with an RSE of 19.71 percentage points (p.p.) (R=0.66), with a non-significant improvement gained from applying a 3x3 smoothing filter to the coral cover layer (RSE=19.38p.p., R=0.67). Further smoothing degraded the correlation. Similar results were obtained from Bawe (RSE=19.72p.p., R=0.59 with 3x3 smoothing filter). Coral cover varied between 0-92% on Chumbe, and 0-83% on Bawe.

Depth was estimated to within 1m on Chumbe (RSE=1.00m) and 1.5m on Bawe (RSE=1.52m). Depth varied between 2.6-11.3m on Chumbe, and 0.6-8.9m on Bawe.

Of the two rugosity variables, only the coarse rugosity was estimated from the satellite data. This was estimated better on Chumbe (R=0.46) than on Bawe (R=0.17). On Chumbe, the correlation degraded significantly with a coarsening of the spatial scale to pixel sizes of 8 and 12m, but then improved again with pixel sizes of 20 and 50m. On Bawe, the trend was toward lower correlations with increased pixel size.

Habitat diversity was estimated very poorly, with the highest correlations R=0.14 on both reefs.

Remotely sensed coral cover and fish

The correlations that remotely sensed coral cover obtained with the fish variables is much weaker than that obtained by in-situ observed coral cover. The influence of scale reflects the accuracy of the prediction of in-situ coral cover values, peaking at a 15 meter radius (Fig. 3).

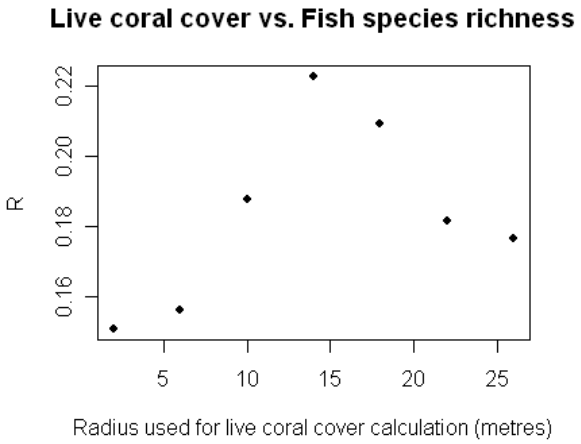

Figure 3: Correlations between fish species richness and remotely sensed coral cover at different spatial scales. Correlation with coral cover observed in-situ: R=0.58. Data from Chumbe. Optimum radius is 15 meters at Bawe, with similar correlation coefficients.

Remotely sensed rugosity and fish

Similarly, remotely sensed rugosity is correlated much weaker with the fish variables than either coarse rugosity (R=0.40, Bawe) or fine rugosity (R=0.37,

Bawe) measured in-situ. Remotely sensed rugosity obtains the highest correlation with fish species richness at small pixel sizes (R=0.22 at 4m pixel size, Bawe), the correlation degrading with increasing pixel size (Fig. 4).

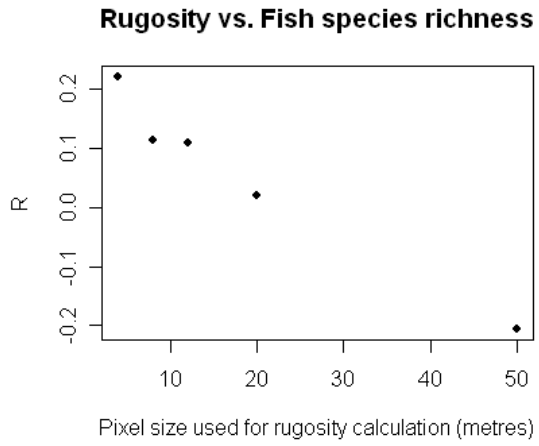

Figure 4: Correlations between fish species richness and remotely sensed rugosity calculated at different spatial scales. Correlations with other fish variables showed similar trends. Data from Bawe.

Remotely sensed habitat diversity and fish

Habitat diversity, however, showed a different trend. The in-situ habitat diversity variable had low correlations with all fish variables ($R \leq 0.14$), but when calculated on the basis of classes in the habitat map the correlations improved, reaching a peak at a radius of 30 meters ($R \leq 0.37$) (Fig. 5).

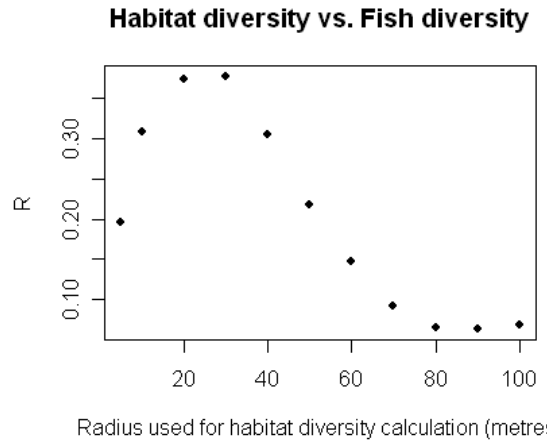

Figure 5: Correlations between fish diversity and remotely sensed habitat diversity calculated at different spatial scales. Correlations with other fish variables showed similar trends. Correlation with habitat diversity calculated on the basis of in-situ data: R=0.14. Data from Chumbe shown, data from Bawe show overall lower correlation coefficients, and two peaks at radii 10 and 50 meters.

Model comparison

The results from the OLS and GAM models, based exclusively on remotely sensed habitat variables, are shown in Table 2. A comparison reveals that models based on in-situ data generally outperform remote sensing-based models slightly, the one exception being diversity on Bawe.

Dependent fish variable	OLS	GAM	OLS BROKEN STICK
Chumbe: Adj. R^2 / Residual Standard Error			
Species richness (species)	0.491/5.76	0.458/**4.40**	0.502/5.70
Biomass ($g/100m^2$)	0.385/3255	0.375/**2109**	No trans.
Diversity (Shannon Index)	0.401/0.59	0.381/**0.43**	0.272/0.65
Bawe: Adj. R^2/ Residual Standard Error			
Species richness (species)	0.397/5.45	0.472/**3.72**	0.465/5.13
Biomass ($g/100m^2$)	0.141/1269	0.248/**763**	No trans.
Diversity (Shannon Index)	0.395/0.70	0.521/**0.44**	No trans.

Table 2: Summary of OLS, GAM and broken stick models based on remotely sensed habitat variables. "No trans." indicates that none of the variables were transformed, and results therefore similar to the ordinary OLS models. Note that the "broken stick" OLS model for diversity on Chumbe performs worse than the ordinary OLS model.

Discussion

This study provides a detailed investigation of habitat-fish relationships. The non-linear nature of several of the relationships provides interesting insights into the effects of habitat variables, e.g. showing how increasing coral cover is associated with increasing species richness, but only up to a 40% cover. For modeling purposes these non-linear relationships render linear models inappropriate, and suggest the use of GAM or other non-linear models.

Remote sensing, based on IKONOS data, was able to map both coral cover and depth fairly accurately. Depth mapping with IKONOS data has been investigated in many studies, but mapping of coral cover has remained difficult with multispectral data. We assume that the very low cover of algae on the two studied reefs has contributed to coral cover being mapped with high accuracy (<20 p.p. RSE).

Our IKONOS data were unable to map rugosity and habitat diversity accurately at the spatial scales at which these variables are observed in-situ. For rugosity, the scales mappable by IKONOS (pixel size 4 meters) have weaker correlations with fish biodiversity variables than visual in-situ estimates.

Inspection of rugosity maps illustrated that beyond the smallest spatial scales, rugosity values were overwhelmingly influences by their proximity to the reef edge, which may be the reason for the improved correlations of rugosity calculated with pixel sizes of 20 and 50 meters. In addition, the image from Bawe suffered from high-frequency noise that reduced the quality of the depth estimation, and hence the rugosity calculation.

Similar to rugosity, we were unable to accurately estimate the habitat diversity as measured in-situ, using the satellite data. However, when measured at scales accessible to remote sensing, but not to in-situ observation, habitat diversity showed improved correlations with the fish variables. This highlights an important use of remote sensing in reef studies: measuring ecologically relevant variables, such as habitat diversity, at their most meaningful spatial scale, which may be inaccessible to traditional field studies.

Optimum spatial scales

Our results are somewhat similar to those reported by Purkis et al. (2008) from Diego Garcia, who found that rugosity was most strongly related to the fish community when measured at radii ≤20 meters, and habitat diversity (quantified as evenness) most strongly related at radii 40-80 meters. Pittman et al. (2007), working in Puerto Rico, similarly found rugosity most strongly related to fish species richness at scales of 42.5 and 22.5 meters (half side lengths of square window). It thus seems that the optimum scales are fairly constant between locations, suggesting that these spatial scales have an ecological basis that is similar for the fish communities studied at these three locations.

Future study directions

The influence of habitat variables will be studied in relation to the presence/absence of individual species or the abundance of families or functional groups. This may yield greater insights into their ecological meaningfulness, which is not revealed by studying their influence on aggregate biodiversity measures as presented in this paper. The analysis of spatial scales will be included in this work, in order to attempt to explain the ecological basis for the optimum scales observed in this and other studies. Regression trees will be explored as a way to deal with the non-linear relationships between habitat and fish variables. The trees will be tested against the described models, and cross-validation applied to ensure robustness of all models.

Finally, the models will be applied to prediction of biodiversity variables in other protected and unprotected areas in Zanzibar.

Abstract. In December 2005, the Airborne Visible Infrared Imaging Spectrometer (AVIRIS) was flown over Puerto Rico and the U.S. Virgin Islands for assessment of the 2005 Caribbean coral reef bleaching event. The resulting hyperspectral imagery is being used as the foundation for evaluating coral distribution and health in these areas. Image processing for this analysis consisted of an important pre-processing phase, followed by a spectral-based benthic classification phase. A critical aspect of the pre-processing was correcting for an adverse stray-light anomaly present in the imagery. The anomaly is characterized by higher than expected radiance values near the center of each flight line accompanied by a small decay of radiance values near the left edge of each flight line. The anomaly is present in AVIRIS imagery acquired from 2004-2006 and is most noticeable over water features in the near-infrared channels. We present an overview of the entire pre-processing phase, including suppression of the stray light anomaly and the edge decay, as well as sun glint removal and atmospheric correction.

Key words: AVIRIS, stray light, sun glint, atmospheric correction

Introduction

Spectral information from corals and other associated habitat components can be detected through a clear shallow water column using remote sensing instruments. Spectral discrimination of reef bottom types (i.e., coral, algae, and carbonate sand) is possible using field spectroscopy methods (Hochberg and Atkinson 2000; Hochberg et al. 2003) as well as using spectral image analysis techniques (Goodman and Ustin 2007; Hedley and Mumby 2003; Mobley et al. 2005). However, only visible light penetrates deeply into the water column, water properties are typically variable, and the benthic surface is spatially heterogeneous. Thus, due to the spectral complexity of this environment, data from imaging spectrometers with multiple spectral channels in the visible portion of the electromagnetic spectrum, such as the Airborne Visible Infrared Imaging Spectrometer (AVIRIS), can potentially provide better maps of benthic types, compared to multispectral sensors.

Analysis of benthic composition using remote sensing requires a number of pre-processing steps to convert the measured at-sensor radiance into reflectance data. This is because at-sensor radiance represents a complex combination of absorption and scattering features from the atmosphere, spectral interactions at the air-water interface, absorption and scattering from the water column and reflectance from the benthic surface. The sensor system itself can also add artifacts and noise during the recording process. As an important first step in effective image analysis, pre-processing is utilized to remove the confounding effects of sensor artifacts, atmospheric influence, and specular reflection from the water surface (i.e., sun glint).

We present a series of techniques utilized for pre-processing AVIRIS imagery acquired in 2005 from Puerto Rico and the U.S. Virgin Islands. Output derived from these techniques is in the format of remote sensing reflectance at the water surface, which is subsequently being used to retrieve bathymetry and water properties and to classify the benthic substrate following methods adapted from Goodman and Ustin (2007). The resulting image products are being utilized in conjunction with field surveys to assess coral distribution and health following the 2005 bleaching event (Guild et al. 2008).

Materials and methods

In mid-December 2005, AVIRIS was flown on the NASA Twin Otter over sites in SW Puerto Rico and the U.S. Virgin Islands to investigate impacts from the 2005 coral bleaching event. The Twin Otter was flown at an altitude of 3.5km, producing an image spatial resolution of approximately 3.1m. A handheld spectroradiometer (GER1500, Spectra Vista

Corporation) was concurrently used in the field to acquire reflectance measurements of the water surface at three locations.

While AVIRIS has a long history of improvements while providing high-quality imaging-spectrometer data (Green et al. 1988; Carder et al. 1993; Green et al. 1993; Sarture et al. 1995; Clark and Swayze 1996; Eastwood et al. 2000; Green and Boardman 2000; Green and Pavri 2000), in some situations the data still contain unwanted features that need to be corrected. In 2004, a new foreoptics section was installed on the system. This significantly improved the signal-to-noise ratio of the instrument (i.e., increased instrument performance), particularly in the visible portion of the spectrum, but introduced a stray-light anomaly in imagery acquired from 2004-2006. The stray light is a portion of light that has entered the instrument and should be recorded at a given measurement location (i.e., pixel), but is further reflected within the instrument, becomes mixed with other light, and subsequently inappropriately recorded at a different location. The resulting anomaly is visually apparent as a "glow" of incorrect data surrounding a stripe of "good" data where the stray-light effect is not present (Fig. 1a). Because this anomaly is a function of stray light from nearby pixels, and because land features typically reflect light strongly in near-infrared wavelengths, the anomaly is stronger at the land-water boundary and most significant in the near-infrared channels (750-1300nm). Although the anomaly is minor in the visible-wavelength channels (370-700nm) (Fig. 1b), where aquatic remote sensing is primarily focused, artifacts in the near-infrared can be transferred to the visible channels via sun glint suppression and atmospheric correction algorithms. While the impact of the stray-light effect is only a few percent of the relatively stronger signal over land, it can be as much as ~40% of the significantly lower signal over water areas adjacent to land.

Pre-processing the AVIRIS imagery for subsequent benthic analysis included suppressing impacts of the stray-light anomaly, correction of an unexplained edge decay feature, suppression of sun glint and finally atmospheric correction.

The stray-light anomaly was independently suppressed for each of the affected near-infrared channels (Fig. 1c) using an adaptive line-by-line correction that differentially adjusts the left and right sides of the image. The two sides were corrected separately because the anomaly was found to be different on each side. Correction was achieved by first using a moving window (101 along-track pixels by 30 across-track pixels) to calculate the mean of the central stripe of "good" data and the means of the "glow" adjacent to the left and right of the stripe for each line. The values for the individual pixels on each side of the image were then reduced as a function of the difference between the mean of the central stripe and the mean of the respective left or right "glow", scaled by the pixel distance from the central stripe (Fig. 2).

The decay feature along the edges of each image impacted the first seventy pixels (Fig. 3) and the last pixel in each row. This limb effect was corrected by first computing the across-track column means for a designated training area within deep water in each flight line, which was assumed to be spectrally homogenous (i.e., a flat field). Scale factors were then calculated to normalize each of the column means to a single mean for the training area. The resulting scale factors were used to adjust the values of the first seventy pixels and the last pixel of each respective flight line, thus making the edge pixels consistent with the more central pixels (Figs. 1c and 3).

Sun glint was suppressed (Fig. 1d) using a spectral normalizing procedure following the Hedley et al. (2005) variation of Hochberg et al. (2003). In this method the slope of the regression line, b, between pixel values from a NIR band (750nm) and each of the visible bands, i, is computed over a training sample containing sun glint. This slope is then used to reduce the values in each visible band at each pixel location, relative to the difference between the NIR-band minimum value within the training area, L_{NIRmin}, and the location-specific NIR value, L_{NIR}. For each band i, the output pixel value, $L'(i)$, is then:

$$L'(i) = L(i) - b(i)[L_{NIR} - L_{NIRmin}]$$

Atmospheric correction was performed using Tafkaa, an algorithm developed at the Naval Research Laboratory designed to address the confounding variables associated with performing atmospheric correction for shallow aquatic applications (Gao et al. 2000; Montes et al. 2001; Montes et al. 2003). The Tafkaa algorithm includes different aerosol options (none, continental, maritime, or urban) and a number of atmospheric gaseous absorption calculations (water vapor, carbon dioxide, ozone, nitrous oxide, carbon monoxide, methane, and oxygen). The algorithm was implemented using an option to retrieve per-pixel reflectance values based on pixel-specific solar illumination angles and AVIRIS viewing geometry, which provides a more explicit solution to the atmospheric correction calculations. Output was in the units of remote sensing reflectance at the water surface.

As a final step, the imagery was georectified using the internal geometry models (IGMs) and geographic lookup tables (GLTs) provided as standard ancillary files with the AVIRIS imagery (Fig. 4).

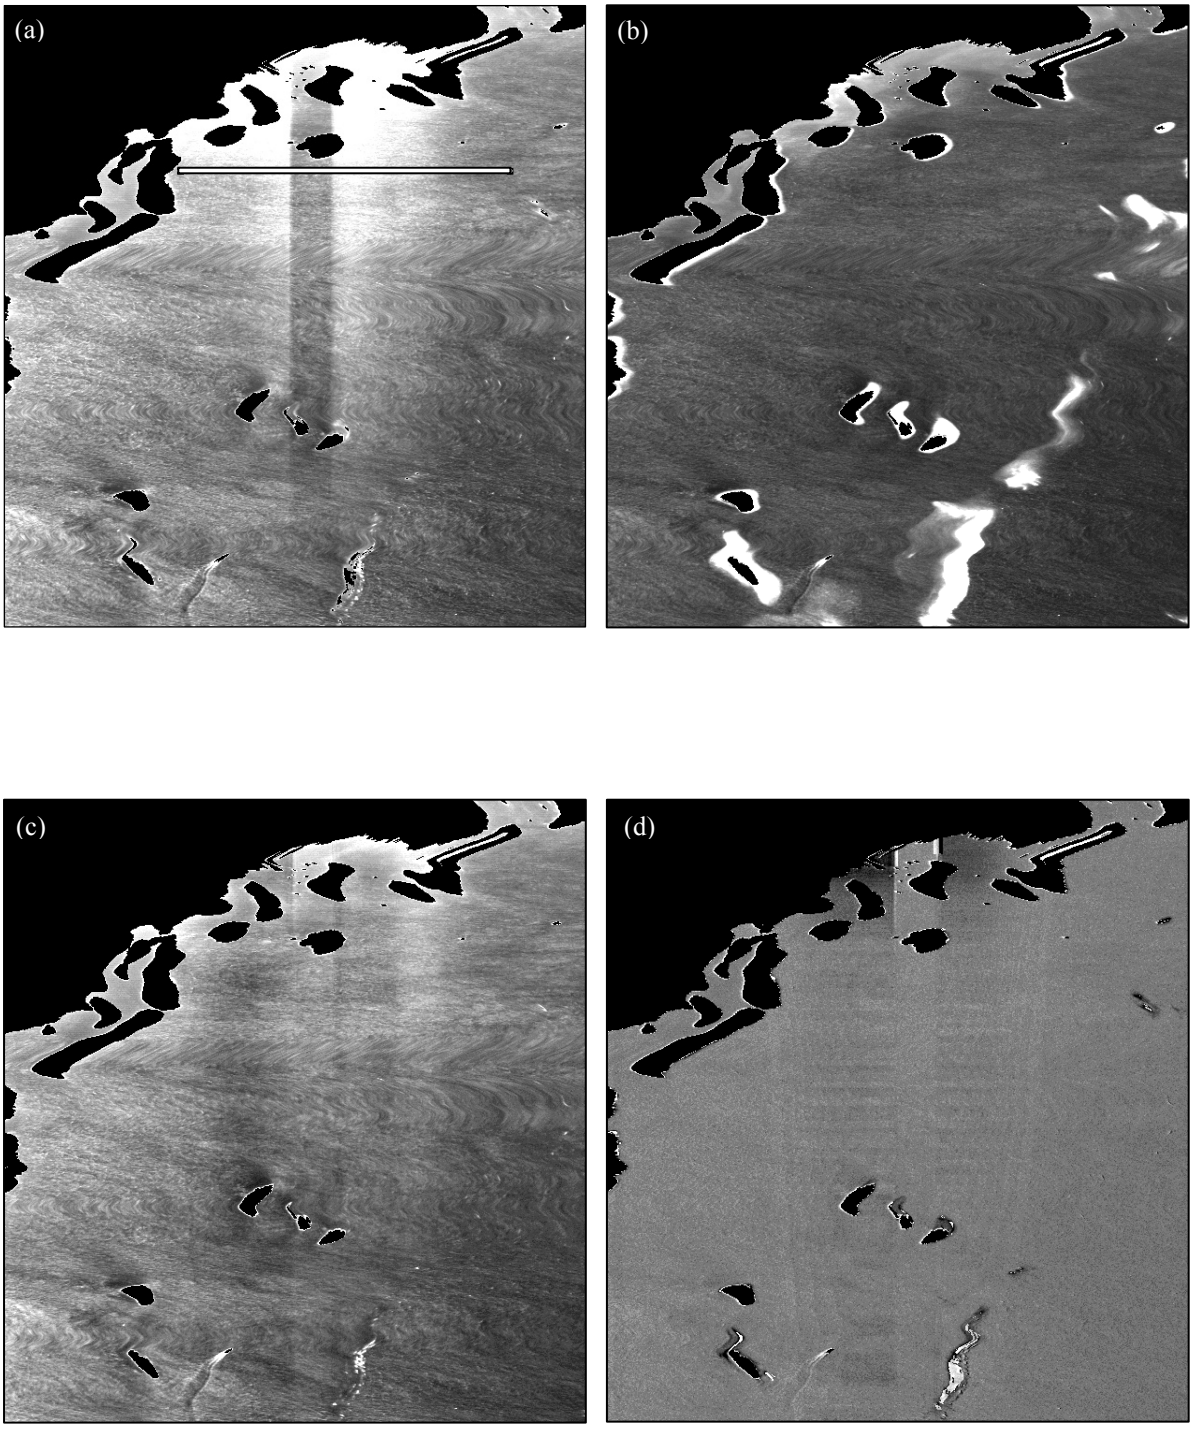

Figure 1. (a) Channel 55 (864nm, near-infrared light) within a non-georectified AVIRIS flight line subset over La Parguera, Puerto Rico. In this flight line, the stray-light anomaly was present only in the near-infrared channels. The long white box is the location of the profile shown in Fig. 3. (b) Channel 35 (672nm, visible red light). The stray-light anomaly did not affect the visible channels. (c) Channel 55 after stray-light suppression and limb correction. (d) Channel 55 after stray-light suppression, limb correction and sun glint suppression.

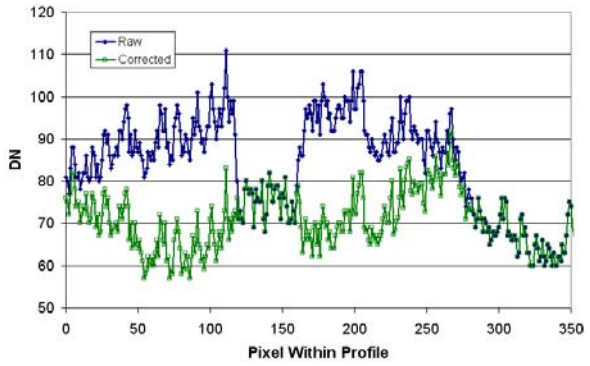

Figure 2. Cross-section profile of stray-light anomaly (from Fig. 1a). The profile shows that the digital numbers (DNs) in the relatively dark central band are similar to the background values near the edges of the swath and that the anomaly decays in magnitude away from the center of the image. The noise is due to sun glint. The corrected values were the result of adjusting the raw values to match those within the central band.

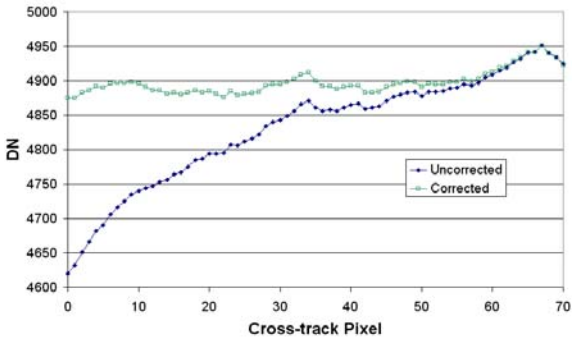

Figure 3. Deep water example of 10-channel averaged DNs within the training area (wavelengths 414-510nm) before and after limb correction. Only the first 70 pixels out of 677 are shown, demonstrating the correction on the affected side of the image.

Results

The most problematical pre-processing step was the stray-light correction, due to the variability of the effect. The magnitude of the stray-light contamination in the water depended on the proximity to land, i.e., the stray-light source, relative to the orientation of the flight line, since the amount of adjacent land determined the magnitude of the stray light. The correction estimation was further complicated by the coast line as well as the presence of patch reefs and sun glint near the coast. For the example given, Fig. 1a, and the corrected, Fig. 1c, the asymmetrical nature of the coastline and the "glow", and occurrence of small islands near the coast led to an incomplete removal of the anomaly. Generally, the post-correction values adjacent to the central stripe matched at the boundary and merged well to the magnitude of the background values (Fig. 2).

Limb corrections resulted in flatter cross-track profiles at the flight line edges (e.g., Fig. 3), which are expected for regions within the imagery that contain only water, i.e., the data are more correct. Also, this improvement should produce better mosaics when the flight lines are stitched together.

Suppressing the sun glint prior to the stray-light and limb corrections was not possible because much of the area with the stray-light contribution would have been considered glint, when the spurious values were due to a separate cause. Ideally, the sun-glint and atmospheric corrections should be performed concurrently, because they affect each other, but incorporating the atmospheric correction processing into the sun-glint suppression program was not possible.

Once all the pre-processing steps on the AVIRIS data were completed (Fig. 1) and the imagery was georectified (Fig. 4), image spectra were extracted from three locations where surface reflectance was measured concurrently in the field (Fig. 5). The AVIRIS-derived reflectance values were somewhat low compared to the field data for all three of the field sites at that location, but generally indicated good agreement between the image data and field measurements. More field data of water-leaving reflectance measurements from other locations would have allowed for better comparisons of the AVIRIS data to field conditions, but with limited equipment and a primary focus on collecting benthic reflectance measurements for habitat mapping, only limited data were available for the water surface.

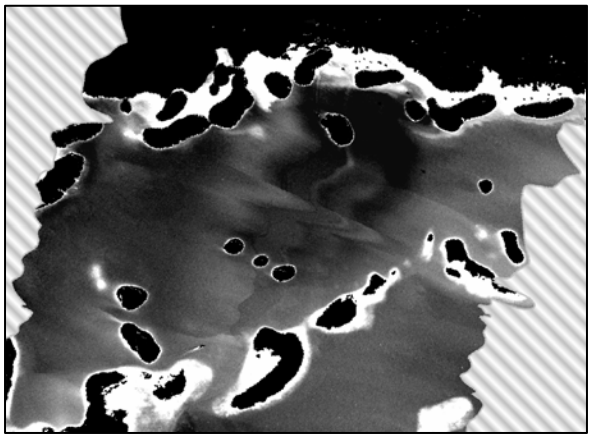

Figure 4. Channel 35 (672nm, red light) subset of sample image following complete pre-processing scheme. The wavy edges are an artifact of, primarily, the roll correction.

Discussion

As a research instrument, AVIRIS has undergone numerous changes and improvements over the years. The foreoptics section change implemented in 2004 improved overall sensor performance, but resulted in an unfortunate stray-light anomaly (note the stray-light anomaly was fixed for the 2007 flight season and only impacted data in the 2004-2006 seasons).

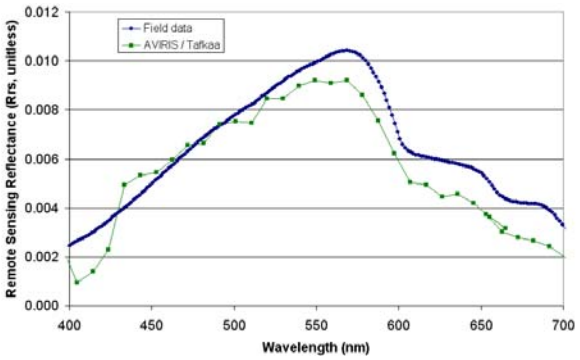

Figure 5. Image-derived and field-measured, remote sensing reflectance (R_{rs}) for one of three near-shore water sites. On average, the image-derived values were 16% lower than the field data.

We have presented an overview of the methodology used for correcting this anomaly, as well as a summary of other steps used for pre-processing 2005 AVIRIS imagery of Puerto Rico and the U.S. Virgin Islands. The corrected imagery is ready for further analysis and represents a valuable resource for evaluating coral reef conditions at the end of the mass coral bleaching event in 2005. Current analysis is focused on using the imagery to derive water properties, bathymetry, and benthic classification products (Guild et al. 2008). Results from this analysis have been consistent with additional field observations and measurements, thus lending further support to the efficacy of the presented pre-processing scheme.

Acknowledgements

Rob Green and Michael Eastwood (NASA Jet Propulsion Laboratory) provided information throughout this analysis to help us understand the features in the AVIRIS data and their team used their engineering expertise to fix the cause of the stray light. This analysis was supported by the NASA under Grant No. NNH06ZDA001N-IDS issued through the Science Mission Directorate's Earth Science Division. The AVIRIS airborne mission was funded by NASA's Ocean Biology and Biogeochemistry Program. Goodman's work on this project was supported in part by the Bernard M. Gordon Center for Subsurface Sensing and Imaging Systems (Gordon-CenSSIS), under the Engineering Research Centers Program of the National Science Foundation (Award Number EEC-9986821).

Abstract. Map products derived from remote sensing technology increase our understanding and ability to manage tropical marine environments. The enhanced mapping capabilities of hyperspectral sensors are well understood; yet technology uptake, particularly for large scale tasks, has been slow. The study presented represents one of the largest hyperspectral projects to date, and paves the way towards increased use of this technology. Hyperspectral CASI-550 imagery and multispectral QuickBird imagery, was acquired over 3,168 km^2 of the Farasan Islands. In addition to the typical image processing steps, inopportune water condensation in the CASI sensors lens necessitated further processing to remove an across-track artifact. We present a simple protocol for correcting this abnormality, utilizing an abundance of optically deep water to model and correct the error. Investment in optical, bathymetric, and other supporting field data, along with the acquisition of the QuickBird imagery was vital. Data pre-processing facilitated thematic mapping with accuracy comparable to other studies, while allowing the use of spectral unmixing to discriminate coral from within algae dominated patches in shallow water (0-5 m) environments. The unmixing model proved robust, was readily adaptable to the CASI sensor and provides additional habitat information beyond the level of thematic mapping alone.

Keywords: CASI, QuickBird, remote sensing, coral reef, spectral unmixing

Introduction

The use of optical remote sensing technology to characterize reefscapes has increased in recent years. Drawing on a global dataset of reflectance spectra, Hochberg et al. (2003) showed that most reef components can be spectrally grouped into 12 fundamental categories; brown, green and red fleshy algae; calcareous and turf algae; brown, blue and bleached coral; gorgonian/softcoral; seagrass; terrigenous mud; and sand. As such, spectral discrimination is sufficient to classify basic reef components such as coral, algae, and sand, but insufficient at the species level. The vast majority of work to date has concentrated on multispectral, predominantly satellite based sensors (e.g. Landsat TM, IKONOS, QuickBird), which offer reliable data relatively cheaply. However, multispectral sensors collect data within only a few discrete bands and this spectral paucity may preclude discrimination of some habitat components. Hyperspectral sensors (e.g. AVIRIS, AISA, CASI, PHILLS), by contrast, provide higher levels of spectral detail. This may enable classification of image pixels into a greater number of descriptive classes, or facilitate deriving the relative fractional contribution of different spectral-endmembers (Goodman and Ustin 2007).

This study utilizes both Compact Airborne Spectrographic Imager (CASI)-550 hyperspectral imagery and QuickBird multispectral imagery. Using standard image processing techniques, a single integrated map product is achieved by merging classification output from the two different sensors. However, an unfortunate across-track spectral abnormality, later diagnosed as a lens condensation issue, was identified on receipt of the CASI-550 imagery. Across-track errors are typically caused by vignetting, instrument scanning, or non-uniform illumination effects, and can usually be corrected using standard processing algorithms. The across-track irregularity in this data proved more complex and necessitated a customized correction approach.

Studies to date mostly favor the descriptive class approach, where each pixel is assigned to a single thematic class, and forgo sub-pixel unmixing techniques. We examine both approaches in meeting two objectives: 1) the production of large-scale thematic habitat maps describing functionally important carbonate and sediment systems; and 2) an assessment of how spectral unmixing techniques might be applied to a CASI dataset to complement thematic information. To meet the latter objective, Goodman and Ustin's (2007) unmixing model

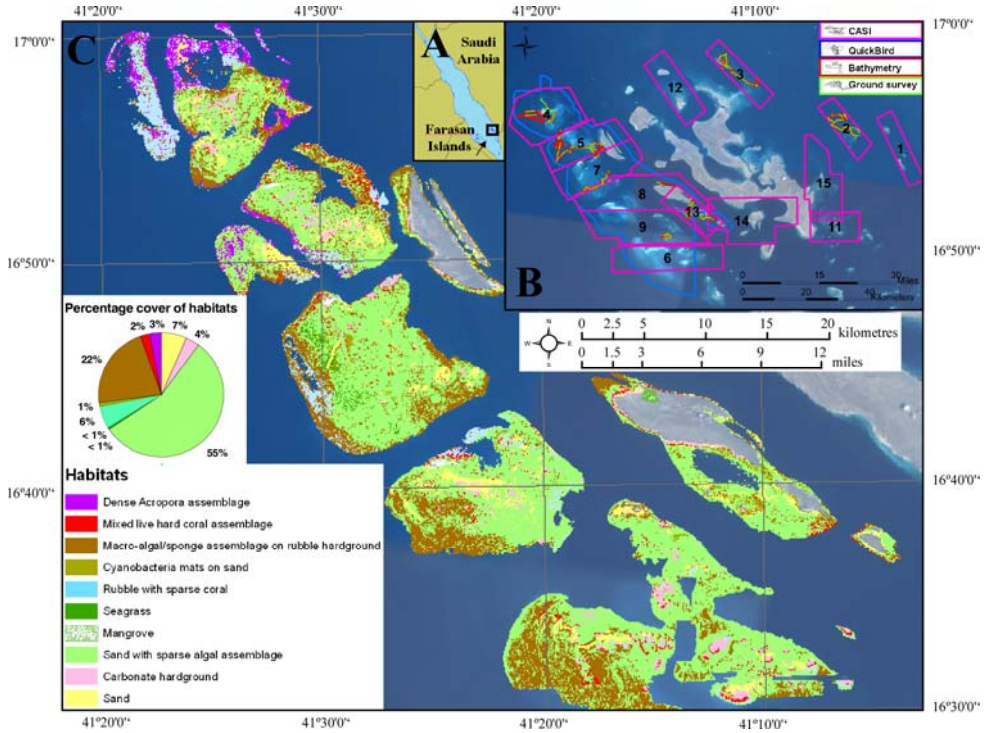

Figure 1: A) Position of the Farasan Islands, Saudi Arabia; B) Coverage of CASI imagery (magenta), QuickBird imagery (blue), bathymetric tracks (red) and ground survey points (orange); and C) Habitat map for the Western Farasan Islands produced using CASI hyperspectral and QuickBird multispectral imagery, along with percentage breakdown by habitat. Map accuracy: P_0= 82% (95% confidence intervals of P_0 are 77% and 86%), T= 79% (95% confidence intervals of T are 75% and 85%).

was employed. The approach combines a semi-analytical inversion model with linear spectral unmixing to extract sub-pixel information on sand, coral and algal composition, while simultaneously deriving information on water properties and bathymetry.

Materials and Methods

Image acquisition: In May 2006 3,168 km^2 of CASI image data were collected in the Farasan Islands, Saudi Arabia (Fig. 1A and 1B). The data presented here comprises the western bank region (Areas 4-9); approximately two thirds of the total area acquired. Data were collected at 1.5 m pixel resolution, with 19 bands assigned between 400 and 660 nm and 2 bands within the near-infrared (NIR) region, representing a non-contiguous 21 band hyperspectral dataset. Band width (FWHM) ranged from 3-7.6 nm. The instrument was mounted on a Cessna aircraft, fitted with differential Global Positioning System (dGPS), integrated to a gyroscope measuring aircraft position and movement. CASI imagery was corrected to scaled radiance prior to delivery. Augmenting this, 1,637 km^2 of high resolution QuickBird satellite data (eight scenes dating March 2004 through October 2006) were also acquired (Fig. 1B). QuickBird imagery has high spatial resolution (2.4 m pixel) comparable to CASI, but with fewer bands 4 vs. 21 and greater band width (60-140 nm).

Field survey: Field bathymetric, benthic and spectral data collection efforts were combined for maximum efficiency (Fig. 1B). Using Landsat imagery as a guide, ground tracks bisecting areas of high spectral heterogeneity, depth and exposure regimes were selected. This maximized the representativeness and diversity of habitat sampling. Single-beam acoustic sonar linked to dGPS was run continuously during the survey process, producing ~160,000 soundings, later adjusted for tidal height. A subset of 2,967 soundings were then set aside from model development and utilized exclusively for test purposes. A visual census incorporating percentage covers of major habitat contributors (corals, macro-algae, seagrass, sponges, etc) and base substrates was carried out using glass-bottom buckets, snorkel and SCUBA. Sites were chosen at random along the pre-selected ground tracks, though some spectrally distinct features were specifically targeted, producing 1604 ground truth points. A Dive-Spec underwater spectrometer (NightSea LLC) utilizing both artificial and incident light sources, calibrated against a white Spectralon panel (99% reflectance), was used to measure diffuse attenuation, marine and terrestrial endmember spectra, and deep water reflectance. Optical data described the water as intermediate between Jerlov type II and type III, indicative of a slightly turbid tropical environment.

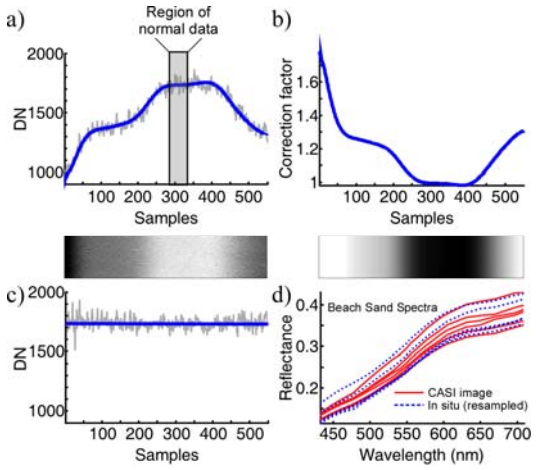

Figure 2: Across-track abnormality correction using optically deep water subset for a blue (506 nm) band. a) Across track abnormality; mean trend shown by bold line, along with region of normal data identified by field spectra comparison and image; b) Correction factor line and image; c) Corrected line and image; and d) Beach sand spectra from corrected imagery and *in situ* optics re-sampled to the CASI spectral response.

Abnormality correction: Fig. 2a illustrates the across-track abnormality, shown as the spectrum of a single band across a single line over deep water. Allowing for sea-surface and wave induced background-noise, this line is expected to have a relatively constant across-track response.

While a region of relatively flat data exists (as indicated in Fig. 2a), the spectral response drops precipitously towards both edges of the across-track array. It was further determined that this response varies across different flight-lines, thus ruling out an array sensitivity issue. Post-collection instrument analysis suggested a lens condensation problem, resulting in water pooling at the periphery of the lens. The greater affect noted towards the edges of the array, and at increased wavelengths, is consistent with this diagnosis. In the absence of a uniform solution based on the sensor, it is necessary to quantify and correct this effect based on the image data, which is difficult for areas with patchy habitats due to the inherently high spectral variation.

Optically deep water has proved useful in modeling within image spectral variation (Hedley 2005). Deep water fortunately exists in all flight-lines of the Farasan Islands. Subsets measuring 500 (along-track) × 550 pixels (across-track) were created and the across-track spectra from each subset were analyzed to determine the position of 'normal' data (Fig. 2a); typically ~70 pixels offset from centre. Mean 'normal' radiance was calculated using a 50 x 500 pixel subset from this region and divided by the mean spectrum of each sample, producing band specific across-track correction factors (Fig. 2b). The process was independently repeated for all 21 bands of each flight-line, and a correction image identical in size to the extent of each CASI flight-line created. Finally, each raw image was multiplied by its respective correction image, to normalize the peripheral regions to the spectral radiance of the central area (Fig. 2c).

Map products: Image processing followed the methodologies outlined in Fig. 3. A thematic map product was produced by first performing independent supervised classifications of the processed CASI and QuickBird imagery and then merging the results into an integrated product (Fig. 3). Field data were categorized into distinct habitat classes based on the dominant benthic coverage (see legend in Fig. 1C). A total of 800 points were used to train a maximum likelihood classification. When either sensor lacked adequate spatial coverage (or in cases where the distortion from the CASI abnormality was too high), the other sensor was used. The red and NIR bands from each sensor were used for mangrove classification and land masking, and benthic classification was based on bands from the blue-green region of the spectrum (CASI: 13 bands; QuickBird: 2 bands). A preliminary analysis was carried out for flight Areas 8 and 9 (Fig. 1B) before expanding the mapping protocols to the whole study area. Comparison of tau accuracy coefficients from 185 randomly chosen field observations suggested higher discriminatory ability using CASI in habitats shallower than 6 m (79% vs 74%) while QuickBird was the more accurate of the two sensors for habitats deeper than 6 m (80% vs 76%). Accordingly, two classifications were performed for each sensor, one classification for depths from 0-6 m and one classification for depths from 6-15 m. In the final map product, the various classifications were merged with reference to image availability, depth priority and context. For accuracy assessment of the final map, 300 points independent from the training process, distributed across the study area, were used. Most points (86%) were less than 6 m in depth, reflecting the dominance of shallow bank-top habitat.

Spectral unmixing: An additional image analysis procedure was used to examine sub-pixel habitat composition. Goodman and Ustin's (2007) spectral unmixing model was adapted to take account of the CASI band configurations. Results were evaluated using a single geocorrected flight-line with extensive ground and bathymetric data. Mean field spectra from the Farasan Islands for sand (n = 10), algae (n = 21) and coral (n = 29) were used as the spectral endmembers in the unmixing model. Derived bathymetry was compared to *in situ* depth soundings and endmember abundance maps were displayed as an RGB false-color composite for field data comparison. Accuracy was assessed using the *in situ* ground survey data.

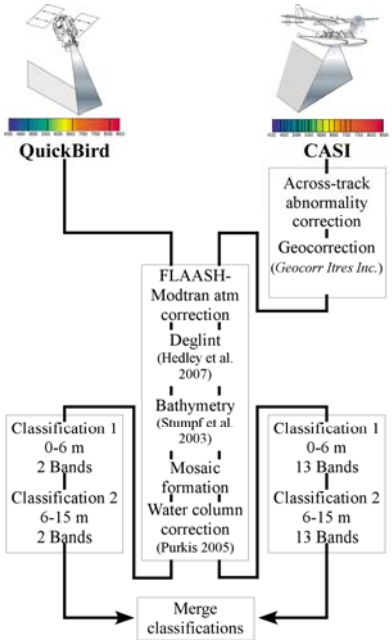

Figure 3: Processing stream for CASI and QuickBird data in producing thematic map product.

Results

The CASI across-track spectral abnormality was effectively removed using the derived correction factors, resulting in realistic spectral response across each flight-line (Fig. 2c). Background noise levels were comparable in magnitude to the raw image. Following further image processing (Fig. 3), image spectra also compared favourably to *in situ* beach sand spectra (Fig. 2d). This allowed creation of a radiometrically consistent mosaic for the study area. The method was successful in all bands for the majority of flight-lines; however, in 5% of cases, line correction was not possible as a flat region of 'normal' data could not be identified. These flight-lines were excluded from further analysis.

The combined sensor approach (Fig. 3) had a good overall accuracy (tau coefficient = 79%), mapping a total of 10 habitat classes. The western Farasan Islands are predominantly sedimentary in nature with 55% of benthos comprised of sand, or sand with sparse algae. Other areas include macro-algae/sponge atop rubble hardgrounds (22%); and rubble with sparse coral cover (6%), often intermixed with dense *Acropora* areas (3%) in the north-west. With the exception of *Acropora*, coral was only classifiable as a mixed assemblage. This comprised only (2%) of the substrate, mostly located in microatoll formations of 1-20 m diameter. Applied to Quickbird data the bathymetric model of Stumpf et al. (2003) compared favorably with actual soundings to a depth of 15 m (r = 0.91, p = <0.001, n = 2,967).

Application of the Goodman and Ustin (2007) unmixing model to the test CASI line was successful overall for investigating sub-pixel habitat composition. The comparison of predicted versus true depth (Fig. 4a) shows accurate depth determination to ~4.5 m (r = 0.83, p = <0.001, n = 161). Spectral unmixing within this depth threshold was also successful (Fig. 4b), having a high apparent overall accuracy of 76%. Small macroalgae patches (bright green) within a sand matrix (bright blue) are clear, as are transition pixels at fuzzy patch boundaries. Of particular note is the correct identification of small but abundant coral colonies at sub-pixel percentage cover, verified by field survey.

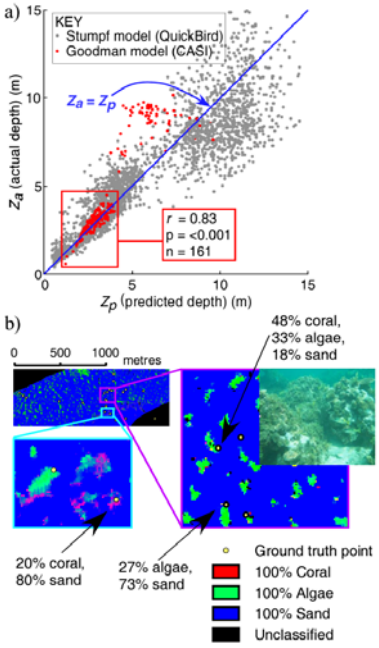

Figure 4: Goodman and Ustin (2007) model applied to CASI data showing: a) Comparison of model derived bathymetry and *in situ* soundings using Pearsons correlation; results of Stumpf et al. (2003) model applied to QuickBird also shown for comparison; and b) False color composite at differing resolutions with percentage coral, algal and sand in the red, green and blue channels respectively. Image typical of patches shown in upper right.

Discussion

The across track processing method (Fig. 2) represents a novel approach to a rare (or rarely disclosed) problem. The need for this correction is an exception and not needed for most hyperspectral acquisitions. The solution is simple, and when followed by standard atmospheric and water column corrections, a high quality image mosaic suitable for habitat mapping can be produced. The method has two processing requirements: 1) image data in a raw format uncorrected for geoposition, pitch, roll, or yaw; and 2) areas of deep water over which to model the spectral artifact. In most cases, the end users of hyperspectral imagery are not directly involved with image collection or pre-processing. Imagery is often delivered as radiometric and geocorrected flight-lines or a flight-line mosaic. In our case, we were able to liaise with our imagery supplier to acquire unprocessed imagery on which to derive

a solution. Deep water is ubiquitous in our study area. This may not be the case for all study sites; however this study supports its inclusion where possible. As all lines were affected to some degree, quantifying the propagation, or not, of error through the above process is difficult. Field optical data compare favorably to fully processed imagery (Fig 2d), and the accuracy of the resultant maps lend support to our technique. Though partly automated, our solution operates on a band-by-band, line-by-line basis, and may therefore be time intensive for large datasets. Most significantly, we were able to recover data to a good standard, allaying any loss of capital investment.

The number of habitats (10), and overall accuracy (82%) compares favorably to CASI mapping elsewhere (e.g. Mumby et al. (1998) 81% for 9 classes, above 20 m depth; Bertels et al. (2008) 73% for 10 classes, above 15 m depth). Though overall accuracy may be biased towards shallow environments, our preliminary analysis suggests accuracy is likely to be >70% throughout. Bertels et al. (2008) demonstrate mapping to a higher number of classes, but there is a clear dichotomy between the number of classes mapped and overall accuracy. The different performance at depth of QuickBird vs. CASI is notable. Given the width of the QuickBird bands, signal is integrated over a greater portion of the spectrum than the selected CASI bands, which cover a more limited spectral range. While this effect is difficult to quantify, newer hyperspectral sensors record contiguous bands over a greater spectral range, have increased signal capacity and are thus expected to perform better. In the multi-sensor mapping approach presented, the use of 10 thematic classes is well suited to integration with QuickBird classifications. Though each sensor produced good classifications independently, the merged approach allowed adjustment for shortfalls in the coverage of either dataset.

Depth derived using the Stumpf et al. (2003) model showed a close relationship with true depth to 15 m. Both this model, and the Goodman and Ustin (2007) bathymetry model, were most accurate in shallow environments (<5 m). Correlation levels compare favorably to other datasets, as well as to similar inversion models (e.g. Bertels et al. (2008) (r = 0.86)). In both studies, model performance declined with depth. This is partially a function of increased light absorbance with depth, but with respect to CASI, there is also likely to be a decrease in the signal-to-noise ratio caused by the spectral artifact.

The outputs of Goodman and Ustin (2007) model indicate that spectral unmixing is both possible and accurate (apparent accuracy = 76%) in shallow environments (Fig 4b). The unmixing model concurs with field survey data in suggesting that an ecologically significant proportion of coral in the Farasan islands are located atop hardgrounds dominated by macro-algae. This is a dominant habitat across the western banks (Fig. 3).

This project demonstrates the utility of hyperspectral technology, despite encountering unexpected processing requirements due to the spectral artifact described above. Agencies often forgo hyperspectral sensors when mapping large geographic areas. However, the two approaches are complementary, providing ecologically relevant information at different hierarchical levels. Spectral unmixing of significant habitat components adds value to conventional mapping, and will lead to the better understanding, and management, of coral reef ecosystems.

Abstract. The health status for Pirotan reef (22°60' N, 70°40' E) located in the Gulf of Kachchh, India, has been assessed using health indicators. Indicators of Pirotan Reef health are temperature rise, increase in macro-algae, over-fishing, high sedimentation rate, human influences, and deposition of mud over reef. Field data was carried out on the reef to collect information about the status and to map benthic cover using the line transect method. Indian Remote Sensing Satellite LISS III sensor data of periods 1998, 2000 and 2005 were analysed to zone the eco-morphological zones of the reef into nine classes with an accuracy of 89% to 92% at 90% confidence level. NOAA AVHRR average monthly SST data was analyzed from 1998 to 2005 (March, April, May and June) to identify the effect of temperature rise on coral reef bleaching. Depositions of sand and mud have increased owing to the high sedimentation rate, sand mining and cutting of mangroves. Coral bleaching and stress have resulted in increased macro-algal growth. The Pirotan reef is under severe degradation as is apparent from the indicators of health. Integrated data of multi-temporal and spectral remote sensing data, SST and field data are important to asses the health of Pirotan coral reef. Although not all deleterious processes can be measured directly (e.g. overfishing), many environmental and ecological coral properties can be measured using remote sensing.

Key words: Coral reef health, multi-temporal, Pirotan Island, remote sensing, sea surface temperature

Introduction

Changes in coral reef health and vitality are sensitive indicators of environmental change. The overall coral death is owing to the thermal stress by anthropogenic global warming, new virulent pathogens, chemical pollution, macro-algal competition and high sedimentation.

A "healthy reef" can be characterized as one with high cover of live corals and short algal turfs and low cover by fleshy algae. Associated indicators of a healthy reef are thus high cover of corals, optimum cover of calcareous algae, short algal turfs, low cover of fleshy algae and good fish diversity. The indicators of a degrading reef include decrease in coral cover, increase in massive rounded corals, increase in coral bleaching, increase in coral disease and macro-algae overgrowth. So, the indicators of the healthy reef are the opposite of a degrading coral reef. Understanding the benthic community structure is central to understanding coral reef health. Measuring the percentage of live coral cover for assessing reef degradation is important indicator for comparisons among coral reef health (Burke et al. 2002).

There are also temporal challenges from the heterogeneous and dynamic variations in coral reef communities over time, requiring long time-series observations with enough frequency to determine the state of health of coral reef ecosystems. Satellite sensors have proved to be useful in providing information on reef geomorphology, and broad scale ecological information such as the location of coral, sand, algal and seagrass habitats with accuracies of around 70% (Green et al. 2000). Satellite and airborne sensors are useful for benthic substrates mapping (Bina et al. 1978) and monitoring ecological change (Zainal et al. 1993).

The sensitivity of reef corals to abnormal elevations in water temperature has been known for many years (Jokiel and Coles 1990). Large-scale bleaching episodes indicate that coral reefs are likely to be one of the first ecosystems damaged or destroyed by global climate change (Hayes and Goreau 1991).

We have evolved an indicator-based approach for monitoring health of reefs (mainly satellite-derivable indicators). The indicators tell about the damage already done, current ecological condition and early warning to the reefs. Early warning indicators are sea surface temperature anomaly, turbidity, and the onset of algae. The ecological indicators are diversity (both floral, faunal and habitat), percentage cover of live and dead corals and the damage indicators are the deposition of mud and sand on the reef, erosion, and phase shift. The non-aligned coral zone (NACZ) is on reef tops normally receiving lower wave energy, where the reef flat is commonly formed from randomly scattered ovoid coral colonies with intervening sand patches (Hopley 1982).

The overall aim of this research paper is the development of a health model for coral reef ecosystems based on remote sensing information. This monitoring system should enable not only the efficient mapping of coral reefs, but also the identification of the reefs that are most endangered. This information will significantly contribute to the progress of protecting and restoring the coral reef environments and will in this way add to the sustainable development of these valuable natural resources.

Material and Methods

The Gulf of Kachchh has an assemblage of different ecologically sensitive ecosystems consisting of coral reefs, mangroves, seagrasses, algae/seaweeds (Fig. 1). Due to its rich diversity and fragile nature, the Government of Gujarat in 1983 declared an area of about 457.92 sq km as the Marine Sanctuary and 162.89 sq km as Marine National Park. Pirotan Island is an Arabian Sea island in the Marine National Park, Jamnagar district of Gujarat state, India. It is located 22 km off the coast, consisting of mangrove, coral reef, seagrasses, algae, invertebrates and low-tide beaches, and has an area of 3 sq km. The center of the island is at 22°60'N, 70°40'E. The Marine National park consists of 42 islands. Pirotan Island is the most popular and is one of the only two islands where visitors are normally permitted.

IRS LISS III data (23 m resolution, with 4 spectral bands: green, red, NIR and MIR) of 1998, 2000 and 2005 have been used for mapping the reef in order to know its ecological status. Required sub-images were extracted from all the data sets and were subjected to geo-referencing using Survey of India topographical maps (base maps). The images were subjected to radiometric corrections and atmospheric correction in the ERDAS IMAGINE environment, prior to implementing a supervised classification. The digital number (DN) values were converted to radiance values using the standard published gain and offset values for the LISS III sensor (Nayak et al. 2003). The images were then subjected to atmospheric correction (Green et al. 2000). We have employed here the Dark Pixel Subtraction (DPS) method. High tides modify and reduce the signature coming from the reef-scape, so it is preferred to select data acquired at low tides and clear sky conditions. We used only the low tide satellite images of the study area, so we did not perform a water column correction.

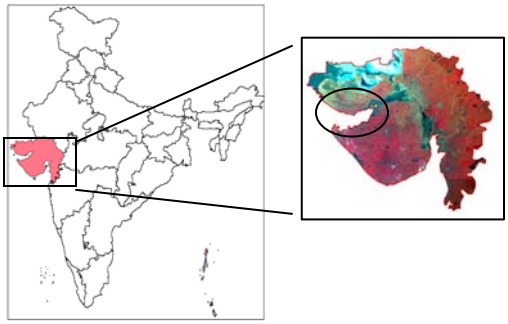

Figure 1: Location of the Gulf of Kachchh study area.

The coral reef habitats were classified using the eco-morphological classification system evolved earlier at the Space Applications Centre, Ahmedabad (Bahuguna and Nayak 1998). On the basis of the spectral properties of the reef features, supervised classification using the Maximum Likelihood classifier was performed for images of all dates. Digital classification accuracy was ascertained by estimating the overall classification accuracy and Kappa Coefficient. Error matrices were generated and the percent accuracy was estimated (at 90% confidence level) based on the number of points verified on ground and the number of failures. During the study period, we collected Line Intercept Transect data (Nayak et al. 2003). Line intercept transects of various lengths ranging from 100 m to 500 m were laid on the reef stretching from the beach seawards to the edge of the reef. After every 20 m, or at each change in zone, observations were recorded. The geographic locations of different points sampled along transect were noted using pre-calibrated Magellion GPS (stand-alone GPS) instrument with accuracy of 10 m. Substrate characteristics were recorded from each sampling location: depth of water, percentage coral, algae and seagrass cover, coral species, size of coral colonies, column of water, and sea surface temperature. We have been collecting ground data for the coral reefs in the Gulf of Kachchh every year since 1998. We collected all the ground data during low tide conditions. During low tide water depth is below 1 m and it is easy to walk on the coral reef from landward to the seaward side (along the transect).

The NOAA/NASA AVHRR Oceans Pathfinder Monthly Sea Surface Temperature images were used to calculate the maximum monthly sea surface temperature of the summer season (March, April, May and June) for 1998, 2000 and 2005.

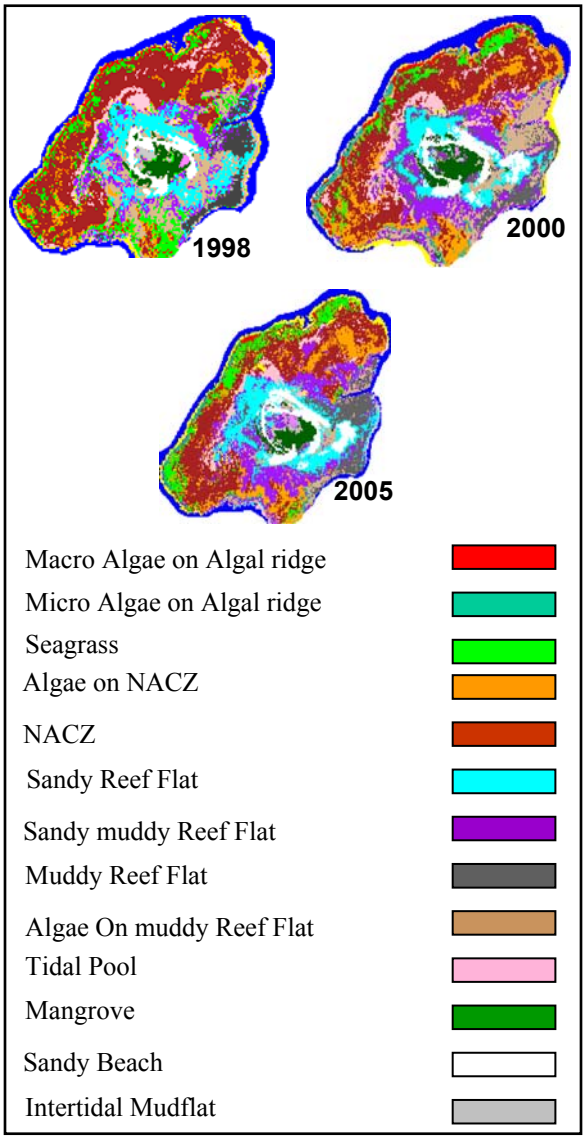

Figure 2: Eco-morphological maps of Pirotan Island reef for 1998, 2000 and 2005.

Results

Reef areas with live coral are predominantly located on the northeastern, western and southwestern areas of Pirotan Island. The entire eastern side has mud deposition. The island itself, located in the center of the study area, is mainly comprised of a horseshoe shaped sand beach, the inward side of which is occupied by mud and mangroves. The reef appears to have been an atoll in earlier times, which has been filled up with mud. The different zones classified using the satellite data were clearly distinguished: algal ridge, mud over reef, sandy muddy reef flat, NACZ, seagrass, algae on NACZ, algae on muddy reef flat (Fig. 2; Table 1). Seventy seven points were verified on the Pirotan reef for the years 1998, 2000 and 2005. There were only five failures in 1998 and 2000 and four failures in 2005. The accuracy was thus estimated to be 89% in 1998 and 2000 and 92% in 2005, all at 90% confidence level. Overall kappa coefficients were 0.85 in 1998 and 2000, and 0.89 in 2005. Major errors in misclassification were because the mangrove class got merged with seagrass, algae and algal ridge, and because muddy reef flat merged with the degraded NACZ.

The NACZ includes the live coral colonies. Live coral cover was determined by using the field data as well as the decrease cover of NACZ by eco-morphological maps during the successive years. Live coral colonies of large sizes and their high percentage are mainly confined to the seaward region of the reef. Maximum coral diversity was observed in the western area followed by northern and northwestern areas. The eastern region is most degraded as indicated by the absence of an algal ridge, presence of thick mud on the reef flat and matty algae on the NACZ.

Eco-morphological Zones	1998	2000	2005
Algal ridge	19.36	45.55	33.33
Seagrass	93.1	38.19	78.93
Algae on NACZ	56.6	122.15	127.17
NACZ	299.57	250.59	295.5
Sandy reef flat	94.00	70.3	138.97
Sandy muddy reef flat	86.7	132.51	176.53
Muddy reef flat	58.67	63.48	88.45
Algae on muddy reef flat	132.3	107.44	58.56
Sandy beach	37.93	61.95	77.29

Table 1: Area (sq km) occupied by the different zones in Pirotan Island reef of 1998, 2000 and 2005.

The areas occupied by the various eco-morphological zones are shown in Table 1. The NACZ characteristically has 25-80% live coral coverage. As the name implies this zone appears first after the algal ridge. On the reef it occupies the greatest area and is broadest in the southwest. Live corals in this zone are mainly *Porites*, *Favia*, *Favites*, *Montipora* and other species. Apart from live corals it also houses a host of faunal species. The inner part of the NACZ has more coral debris, dead coral boulders, pebbles, sand and mud, with negligible live corals. This inner part is considered in degraded condition. The NACZ was reduced in year 2000, which is attributed to the major factors such as anthropogenic influence, sea surface temperature and high sedimentation rate (Table 1).

Algae on muddy sand substrate were mapped on the inner NACZ. The algae on NACZ have been increasing severely from 1998 to 2005 (Table 1). Muddy reef flat follows the NACZ extending up to the Pirotan Island. It is uniformly distributed on all sides and the mud depositions are quite thick (almost 1-2 m in most of the places). The muddy reef flat is also increasing every year (Table 1).

Carpet and matty algae grows on the muddy reef flat. The algae are found to cover larger areas in 1998 and 2000 as compared to 2005 (Table 1). Sand reef flat surrounds the beach on the seaward side with a larger extent on the northwestern side. Mangroves occupy the inward portion from the beach. They are dense and mainly of *Rhizophora* and *Aviceenia* species. The Sargassum is mainly found in NACZ. Onset of Sargassum has shifted from September-October to early December.

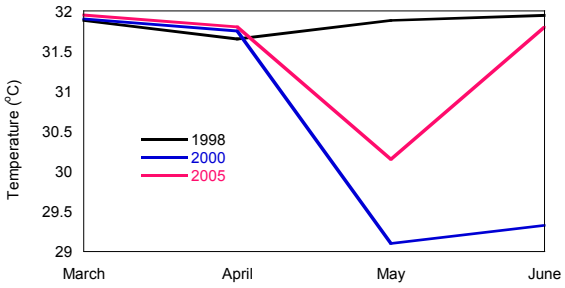

Figure 3: Maximum Sea surface temperature curve of 1998, 2000 and 2005 at the study area.

The effect of elevated sea surface temperature (SST) on the Pirotan coral reef of the Gulf of Kachchh, was monitored during 1998, 2000 and 2005. The temperature varied between 32°C and 29.2°C during summer (Fig. 3). The Pirotan reef areas in the Gulf of Kachchh are shallow, with live coral emerging from the water during low tide conditions. The reefs typically experience comparatively high temperature and seem to be acclimatized to such situations. Nonetheless, the average percentage of bleached corals (12% to 15%) during 1998, 2000 and 2005 has increased. The bleaching of corals occurs in mid March. Massive corals, especially *Porites* sp., were the first to be affected and the other dominant coral species partially/fully bleached were *Acropora* sp. and *Montipora* sp.

Discussion

The results of this study provide several useful points in terms of coral health in the context of reef degradation and disturbance. The recruitment of algal populations is especially critical during coral reef degradation, which usually involves the replacement of hard corals by benthic algae. The loss of live coral cover is often associated with a phase-shift to a system dominated by fleshy algae (Hughes 1994). In the Pirotan reef system the macro-algal (Sargassum) cover on the live coral is increasing every year. During the replacement, algal recruitment is a key but under-recognized step in the invasion and colonization of adult algal populations (Bell and Elmetri 1995). The *Sargassum* on the Great Barrier Reef (GBR), can and will colonize live corals, if conditions such as nutrients or low herbivory are suitable. Available evidence suggests that macroalgal blooms generally will inhibit corals, but also that the mechanisms and outcomes of the interaction vary with different circumstances and life stages. Decline in coral abundance often coincide with increases in macroalgal abundance (Connell et al. 1997). However, other evidence shows variable outcomes of interactions between corals and macroalgae. Corals may also competitively inhibit macroalgal growth (De Ruyter van Steveninck et al. 1988). During the recent massive bleaching on the GBR (early 1998), experimental removal of *Sargassum* canopy showed that the canopy actually protected understory corals from bleaching (Jompa and McCook 1998).

Human impacts, on the other hand, are usually chronic and they degrade water and substratum quality, thus retarding recovery (Wolanski et al. 2003). The concentration of suspended mud, and extent of stickiness and flocculation, can synergistically affect reef benthos organisms after short exposure (Fabricius and Wolanski 2000). In the present study site, the muddy reef flat is increasing due to the heavy discharge of sediments because of human impacts, such as harbor dredging, sand mining, mangrove cutting and overfishing (Nayak et al. 1989; Bahuguna et al. 1992).

River Indus is the major source of the suspended sediments in the Gulf of Kachchh (Deshmukh et al. 2005). Total coral cover was reduced because of the high sediment influx due to cutting mangroves and sand mining (GEC 1997). The eastern side of the gulf exhibits vast areas of dead corals giving a clear indication of mass mortality. Sedimentation is a major controlling factor in the distribution of reef organisms and in overall reef development (Macintyre 1988). Sediment stress has drastically reduced the coral cover and number of species. The effects from sediment influx include partial or total burial of coral colonies, bleaching, and colonization of the coral surface by filamentous blue-green algae and sponges. The reduced light levels also result in domination of the community by deeper fore-reef coral (Acevedo et al. 1989).

Coral reefs are profoundly sensitive to even modest increases in temperature and, in the absence of acclimatization/adaptation, are likely to suffer large

declines under mid-range temperature increase (Berkelmans et al. 2004). The Gulf of Kachchh reefs showed an average of 11% bleached coral with no apparent bleaching related mortality. The incidence of bleaching was not uniform every year, in terms of area and depth, but the pattern was the same. The branching corals recovered quickly after temperature reduction, but massive corals took a longer time. Temperatures in the intertidal reefs of the Gulf of Kachchh commonly reach 36^{o}C and higher in reef areas during summer and the bleaching observed could well be attributable to normal summer bleaching related to seasonal temperature rise (Arthur 2000). It is conceivable that coral species in these intertidal reefs are adapted to such seasonal temperature fluctuations (Gates 1990). According to past study conducted in 1995, estimating benthic cover in the Gulf of Kachcch, reported between 1.2% and 1.4% bleached coral in the summer months before the monsoons (Arthur 2000). This suggests that bleaching levels reported in this survey are considerably higher than normal summer bleaching. Elevated temperatures, even below the bleaching threshold may have significant impact on coral health, retarding growth and reproduction (Jokiel and Coles 1990).

These various indicators can be easily derived from remote sensing systems, which are a cost effective monitoring approach. Multi-temporal and spectral LISS III data have been proven effective to monitor and map the coral reef and extract benthic cover information. SST data products are also very important to monitor the temperature around the coral reef areas. So, integration of remote sensing and field data are important tools to obtain the health status of the coral reef. In the next step, selected indicators will be assigned weights based on their relative importance, and used as input to a model of coral reef health.

Acknowledgement

We are thankful to the Director, Space Applications Centre, and Deputy Director, RESIPA, SAC, Ahmedabad for giving us this opportunity, constant encouragement and facilities to carry out this study. I am extremely thankful to Group Director, MESG for giving me opportunity to do this work and comments. We are also thankful to the Marine National Park Authority at Jamnagar for allowing us to work in the region and supplying us with all logistics support.

Abstract. In 2003 the Aldabra Marine Programme initiated a temperature monitoring network in the southern Seychelles. It currently involves 40 temperature data loggers located at Aldabra, Assomption, Astove and St. Pierre. The annual temperature cycle in the region is marked by a shorter period of winter lows (min 23ºC) between June and October, and extended high summer temperatures (max 30ºC) between December and April. We compare satellite sea surface temperature data from four locations with *in situ* temperature measurements at 6m, 10m and 20m depth. Typically *in situ* temperature measurements do not differ from satellite measurements by more than 1ºC, though on occasions the difference can be as much as 4ºC. SST data is most similar to *in situ* data during the winter, and least similar during the summer. This is most likely due to water column stratification during the summer which is typified by calm weather with weak winds, while during the winter strong south easterly winds reduce stratification. In this case a combination of greater stratification during the summer period, along with periods of cool water upwelling, may in some cases reduce the reliability of SST data for predicting bleaching events.

Key words: sea surface temperature, coral bleaching, southern Seychelles, *in situ* temperature.

Introduction

Satellite sea surface temperature (hereafter referred to as SST) readings are now commonly used to predict where bleaching is likely to occur (Liu et al. 2006, Strong et al. 2002). Temperatures obtained using the Advanced Very High Resolution Radiometer (AVHRR) are supplied online by NOAA's Coral Reef Watch (CRW) in the form of several near-real-time global coral bleaching monitoring tools (Liu et al. 2006). Satellite temperatures used to provide these tools have been exhaustively calibrated with *in situ* sea surface temperature readings from buoys and boats (Reynolds and Smith 1994). The correlation of sea surface temperature readings used in these monitoring tools with real coral bleaching events has also been established (e.g. Cumming et al. 2003, Liu et al. 2003 , Wellington et al. 2001a), demonstrating that they are reliable for predicting when and where bleaching is likely to occur.

The link between satellite SST's and coral bleaching, however, relies on the assumption that surface temperatures will be reflected in some way at the depths where corals live. In most cases this will be a valid assumption, although local oceanographic conditions will determine the depth to which SST readings are likely to be representative. For example, satellite SST readings taken during conditions of low wind speed tend to be less consistent with bulk temperatures due to poor mixing of the surface layer (McAtee et al. 2007). This is due to the fact that satellite SST's record the temperature from the top 10µm to 1mm of the ocean, whereas they are trained to buoy and ship readings that record bulk temperatures within the first metre or so of the ocean surface (McAtee et al. 2007). It is therefore not difficult to imagine a scenario where features such as thermoclines or upwellings could spare corals from bleaching at times when surface conditions suggest it should be taking place.

In 2003 the Aldabra Marine Programme established an array of temperature data loggers at Aldabra atoll, Assomption, Astove and St. Pierre in the southern Seychelles (Downing et al. 2003). These loggers were deployed as part of a monitoring effort following the 1998 El Niño bleaching event. In particular, it was decided that such data should be collected to better evaluate the causes of future bleaching in an area of the world where there is very little monitoring of seawater temperature. The southern Seychelles is also an area where very little temperature data is available for the calibration of satellite SST readings (Reynolds et al. 2005).

Here we compare our *in situ* temperature (hereafter referred to as IST) readings with SSTs from the same

area. These temperatures are not directly comparable as SSTs are obtained from a large area as opposed to our single point temperatures, and our temperature data are obtained from different depths. However, our objective is to compare temperatures obtained by the two methods in order to determine how different they really are, and to establish whether there is a consistent difference between SSTs and IST depth readings. This will allow us to better estimate IST bleaching temperatures from SST data alone. With this in mind we also examine temperatures from both sources during a real bleaching event in the study area that occurred in March 2005.

Methods

In situ data

In May 2003 the Aldabra Marine Programme (AMP) initiated temperature monitoring in the southern Seychelles at 9 sites at Aldabra atoll and at single sites at Assomption, Astove and St. Pierre (Fig. 1). For this study we present results for the period between May 2003 and March 2006. We shall only show results for the outer reef Site 3 at Aldabra, as results are similar for all 9 sites at Aldabra. We also present results for the single sites at the other locations.

Seawater temperatures were recorded using Onset Hobo Pro® and Tidbit® temperature data loggers (accuracy ± 0.2ºC) located at 10m and 20m at all locations, and additionally from 6m at Aldabra Site 3 and Astove. At each depth two loggers (generally one Hobo Pro® and one Tidbit®) were attached to metal stakes at approximately 50cm from the seabed. Having a second logger was found to be a useful way of verifying their stability over time, as data from the two could be compared to look for evidence of drifting. Loggers were set to record every hour (though for the first two years recording was every half hour) and downloaded at approximately 18 month intervals using Onset BoxCar Pro v4.3 software. IST data was then converted to Excel format and daily averages computed for comparison with satellite data. Daily averages were used as night-day temperature differences were very small (normally much less than 0.1°C).

Satellite data

SST data were provided by NOAA Coral Reef Watch. The satellite data used for the comparison were average values derived from a 3 to 4 day composite of night-time sea surface temperatures (SSTs) observed by the AVHRR over a 0.5 by 0.5 degree pixel. For more information on how this is computed refer to http://coralreefwatch.noaa.gov/satellite/methodology/methodology.html#hotspot.

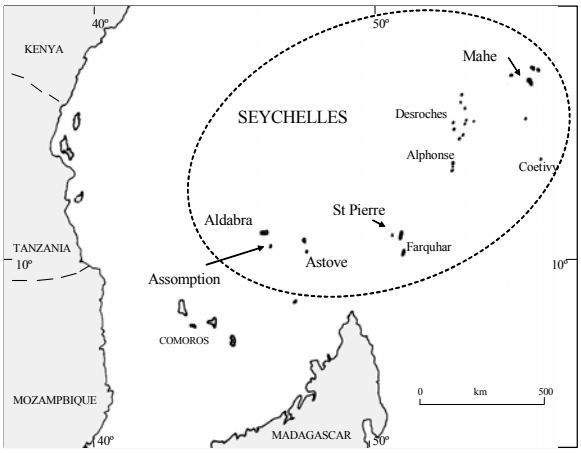

Figure 1: Location of AMP sites in the Seychelles, western Indian Ocean.

Data comparison

In order to compare satellite data with our *in situ* data we matched up our *in situ* average daily temperatures with the last day of the satellite temperature composite. From any composite data the last day is the only date provided. We used data from the satellite pixel closest to each of our sites. Where more than one pixel was available close to one of our sites we obtained an average. Midpoints of pixels used were Aldabra (09ºS 46.5ºE), Assomption (10ºS 46.5ºE), Astove (10ºS 47ºE; 10ºS 47.5ºE; 10ºS 48ºE; 10.5ºS 48ºE) and St Pierre (9ºS 50.5ºE; 9.5ºS 50.5ºE). For comparison of the two temperature sources we subtracted IST from SST readings, giving a bias reading where positive represents cooler IST than SST and vice versa.

Results

Yearly temperature cycle

Temperature at all sites ranged from summer daily averages of approximately 28ºC to winter lows of 24-25ºC (Table 1). There was little difference in temperatures at 6m and 10m, while there was evidence of thermoclines becoming established in the summer between 10m and 20m. Mean differences between the two depths in the summer were greatest for St. Pierre (mean = 0.6°C, SD = 0.4°C, Max = 2.4°C) and less at the other locations (Aldabra mean = 0.4°C, SD = 0.3°C, Max = 1.4°C; Astove mean = 0.3°C, SD = 0.3°C, Max = 1.5°C and Assomption mean = 0.2°C, SD = 0.2°C, Max = 1.0°C). At all locations during the winter period there was little difference in temperatures with depth. The general trend at all sites is one of very stable winter temperatures that do not vary much from day to day and summer temperatures that fluctuate more (see Fig. 2 for a typical example of the temperature cycle, here seen at Aldabra Site 3).

Table 1. Mean summer and winter temperatures (ºC) ± Standard Error of Mean (SEM) for AMP sites in the southern Seychelles for the period May 2003 to present (December 2006 to March 2008 depending on site). n = number of summers or winters, Max = summer maximum and Min = winter minimum temperature ± SD.

Location	Depth m	Summer average	n	SEM	Winter average	n	SEM	Mean Max	SD	Mean Min	SD

SST – IST comparison

The greatest differences between SST and IST temperatures occurred during the summer months for all sites (Fig. 3), with the transition between stratified and unstratified occurring later at Assomption and Astove.

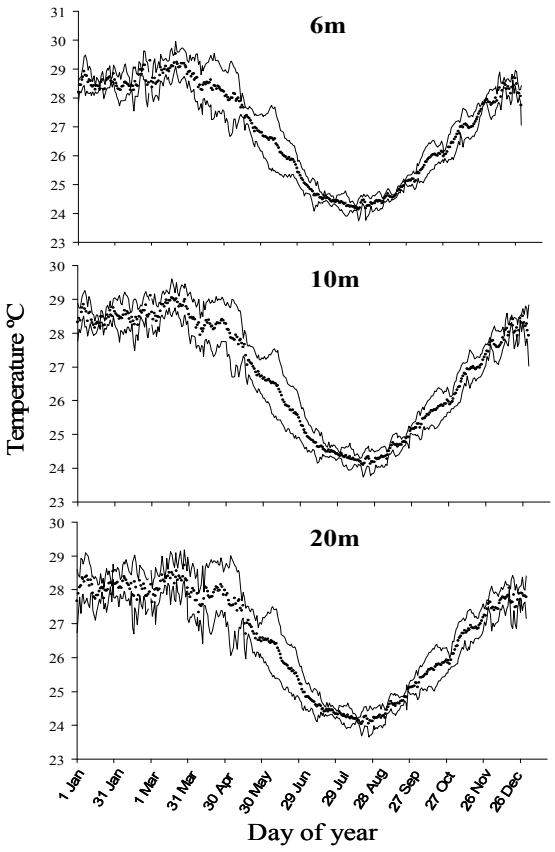

Figure 2. Example of yearly temperature cycle for the southern Seychelles based on mean daily temperature calculated from the period Feb. 2002 to Dec. 2006 for three depths at Aldabra Atoll. Dots represent mean temperatures while solid lines represent ± SD.

We examined the summer period temperatures (January to May) independently as these contrast most from those obtained by satellite. During this period the difference between SST and IST increases with depth at all sites (Fig. 4). The mean difference between SST and IST during the summer period, and at 20m depth, was highest at St Pierre (1.4ºC), intermediate at Aldabra and Astove (0.8ºC), and lowest at Assomption (0.5ºC) (Fig. 4). Points of maximum difference were reached at St Pierre (4.2ºC) and Astove (3.6ºC).

The 2005 coral bleaching event

The AMP conducted coral monitoring surveys at all sites in April 2005. During surveys we noticed diseased corals at Aldabra and Assomption, and coral bleaching at Astove. This extended from the intertidal down to over 30m depth. It included many species including members of the families Acroporidae, Poritidae, Faviidae and Agariciidae amongst others. The bleaching was, however, not intense and in many cases only parts of colonies were affected.

During this period the NOAA satellite products indicated up to 3 degree heating weeks (DHW) and 1.25ºC HotSpots for the area from Aldabra to Astove which suggests likelihood of bleaching in the period leading up to our detection of bleaching. The period of stress did, however, move in from the southeast, indicating that Astove would have been subject to a longer overall period of high temperatures.

Mean summer temperature for the region is approximately 28ºC (Table 2). We have therefore set the bleaching threshold at temperatures greater than 29ºC in line with current thinking that bleaching is likely at temperatures greater than 1ºC above the mean summer temperature (Hoegh-Guldberg 1999). IST data confirms that, while temperatures in 2005 were not excessive for the time of year, there was a

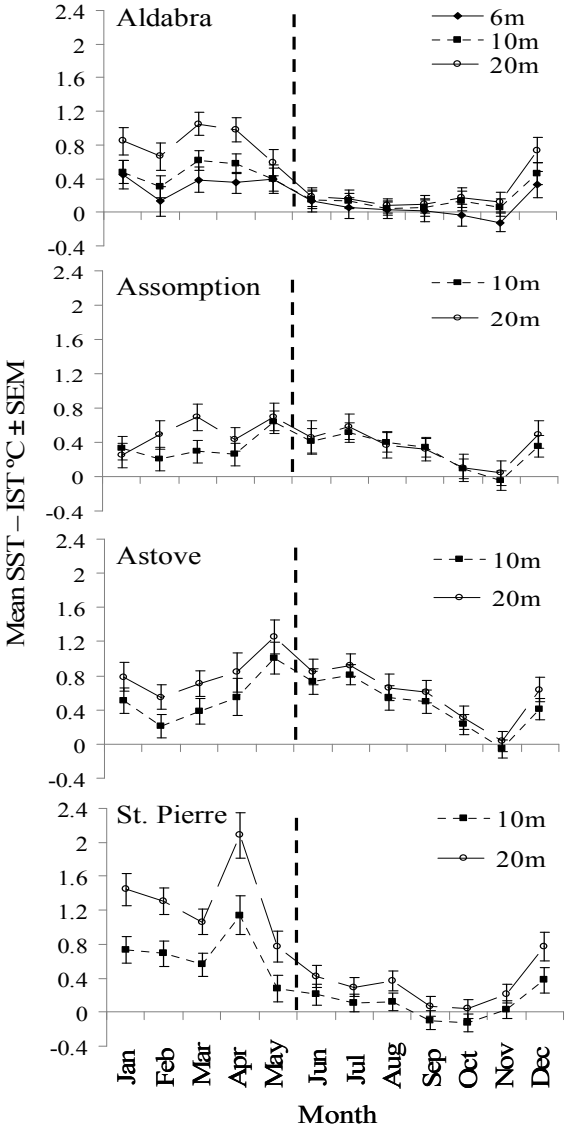

Figure 3. Mean monthly difference ± SEM between SST and IST (10m and 20m depth) temperatures obtained between May 2003 and March 2006. Dotted line represents the start of strong southeasterly winds typical of the winter period.

more prolonged period of high temperatures than for the previous years recorded. In particular, temperatures at Astove were above the 29ºC threshold on a higher percentage of days than at any of the other sites (Fig. 5). When SST data is examined it also shows the prolonged period of stress at Aldabra, Assomption and Astove. However, there is no

Table 2. Mean summer temperatures (ºC) *in situ* for all AMP sites and for SST data. n = number of summers used for estimates, SEM = standard error of the mean.

	SST	6m	10m	20m
Mean	28.5	28.0	28.0	27.7

indication that Astove should be more prone to bleaching than these other locations as the percentage of days above 29ºC is similar at all of the locations (Fig. 5).

In this case SST data did not highlight Astove as a

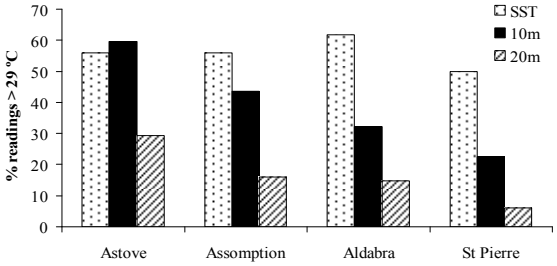

Figure 5. Percentage of days at the sea surface (SST), 10m and 20m depth with mean temperatures in excess of 29ºC at all AMP sites in the summer period leading to the detection of bleaching at Astove (01/01 to 26/04 2005).

potential risk due to several periods, particularly in February, when SSTs were lower than IST temperatures at 10m, and also, though to a lesser extent, at 20m.

Discussion

The IST temperature data we obtained from the southern Seychelles is mostly similar to SST readings provided by NOAA in spite of the differences in depths they represent. The differences between IST and SST data are negligible in the winter. The mean summer differences we obtained at 10m, with a maximum of 0.6ºC for St Pierre, are no greater than differences recorded elsewhere for *in situ* sea surface readings (e.g. Kawai and Kawamura 1997, Wellington et al. 2001b, Sreejith and Shenoi 2002).

In the winter, between June and November, strong south-easterly winds generate rough weather that leads to good mixing, thus explaining the little difference between SST and IST temperatures. Astove and Assomption are exceptions, with the winter IST and SST temperatures only equalising towards the end of winter. This is possibly due to the fact that the AMP sites at these two locations are

particularly well sheltered from south-easterly winds. The summer is typically a period of calm weather with occasional storms. Calm periods last long enough to allow the generation of thermoclines in the water column, as seen by the differences between IST and SST readings, though the temperature differences are generally not very large and the thermoclines appear to be broken down periodically by storms.

The close matching of data is also likely due to the fact that all of our locations are oceanic, with coastlines dropping off to depths in excess of 2000m very close to the shore. In essence this means that our temperature data loggers are behaving not much differently to what you would expect if they were deployed on a line in open ocean. Other SST-IST comparisons have had the confounding effect of shallower coastal waters that can warm above those suggested by SST readings (e.g. Wellington et al. 2001 b, McClanahan et al. 2007).

In spite of the good matching of SST and IST data from the southern Seychelles we must highlight the differences in the data. Generally corals below 10m will be subject to temperatures lower than those at the surface, and at levels that could mean the difference between bleaching or not. This idea is supported by our coral cover data which shows that corals below 20m were much less affected by the 1998 coral bleaching event (Teleki et al. 1999). Conversely, in 2005 we have an example at Astove of warmer water at depth than suggested by SST data. This demonstrates that local conditions can be very different to the general pattern shown by SST readings. We shall address the correspondence of SST and IST anomalies during periods of bleaching in a future publication.

The likelihood of coral bleaching is a function of the length of time that coral is exposed to temperatures above a certain threshold. Our data has shown that at these southern Seychelles sites there is a difference between SSTs and ISTs during the summer months, when the corals are most susceptible to heat-related bleaching. We conclude that while SSTs may give reasonably accurate predictions of bleaching events over a broad spatial scale, they do not always record the water temperatures to which the corals are actually being subjected. Therefore, and in agreement with the view put forward by McClanahan et al. (2007), we believe that in areas of special interest, IST data should always be gathered to more fully understand the patterns of water temperature fluctuations at the depths that really matter: not the surface, but the depths at which the corals live.

Acknowledgements

We thank the Fondation d'Enterprise Total for their part in funding this project. Funding in early years was also provided by CORDIO. The Seychelles Islands Foundation has offered essential support to the AMP since its foundation, and we particularly thank Executive Director Lindsay Chong-Seng, Executive Officer Ronny Renaud, and Chief Executive Officer Dr Frauke Fleischer-Dogley for their support. A Model Framework for Predicting Reef Fish Distributions Across the Seascape Using GIS Topographic Metrics and Benthic Habitat Associations

B.K. Walker[1]

1) Nova Southeastern University Oceanographic Center, National Coral Reef Institute
8000 North Ocean drive, Dania Beach, FL 33004, walkerb@nova.edu

Abstract. Increased topographic complexity has been linked to increased species diversity and/or abundance in many ecological communities, including coral reefs. Several topographic metrics can be measured remotely in GIS using high resolution bathymetry, including elevation, surface rugosity, and seafloor volume within specified areas. Statistical relationships between these data and organismal distributions within mapped habitats can be used to make predictions across the entire bathymetric dataset. In this study a model framework is presented which utilizes statistically significant relationships between reef fish abundance and species richness and GIS topographic complexity measurements for samples within similar benthic habitats to create GIS-based prediction maps of abundance and species richness for the entire seascape. Reef fish associations with GIS topographic metrics were significant and varied between habitats. Model evaluation showed that patterns in the measured data emerged in the prediction data. The results allow for viewing of data trends throughout the seascape, quantification of assemblages in non-sampled areas, and statistical comparisons of areas within the region to support and guide management related decisions. This model framework can be adapted to other communities (e.g. benthic organisms) and/or parameters (e.g. diversity) that relate to topographic complexity.

Keywords: coral reef, Florida, habitat complexity, prediction, reef fish, rugosity.

Introduction

Studies linking small-scale measurements of abundances and species distributions to broad-scale seascapes are the key to understanding and predicting organismal distributions and their dynamics (Heglund 2002). Reef fish studies are often limited to small spatial scales because of logistical and economic constraints; however, viewing the data at larger spatial scales might elucidate unforeseen relationships and patterns (Sale 1998). Furthermore, the need for large-scale spatial analyses of reef fish is growing due to the over-exploitation of marine resources and the need for management and conservation of large areas (Kendall et al. 2003).

Remote sensing allows the acquisition of large amounts of data quickly and economically, providing the foundation for large-scale resource mapping and modeling. These maps are the basis upon which seascape analyses and modeling efforts are constructed (Pittman et al. 2007; Walker et al. *in press*). Previous research has shown that increased habitat complexity/rugosity positively influence reef fish abundance and/or species richness (Luckhurst and Luckhurst 1978; Gratwicke and Speight 2005). Traditional reef fish rugosity studies used an *in situ* measure of topographic complexity that is not practical on large spatial scales (>km²) (McCormick 1994); however, this is now possible by analyzing high resolution 3-dimensional topographic surfaces in GIS (Kuffner et al. 2007; Pittman et al. 2007; Wedding et al. 2008). Several topographic metrics can be measured remotely at various scales in GIS using high resolution bathymetry, including elevation, surface rugosity, and seafloor volume within specified areas.

This manuscript presents a model framework that projects the relationships between reef fish assemblage metrics (abundance, richness, etc.) and GIS topographic metrics for multiple habitats in sampled locations across the seascape. Reef fish are used as a case study to show the model design and demonstrate its capabilities. The model framework design, accuracy, strengths, weaknesses, applications and recommended uses are discussed.

Methodology

A subset of 346 stationary daytime visual fish surveys from a larger effort to acquire a baseline census of the coral-reef-associated fishes in Broward County, Florida, USA (Ferro et al. 2005) was used in this study (Figure 1). The subset was chosen on the basis of location accuracy and agreement with independent

GIS data. The fish surveys were conducted using the Bohnsack and Bannerot (1986) method between 2000 and 2002 along 54 east-west transects, each separated by approximately 0.5 km. The surveys assessed fish species, abundance, and length in a 7.5 m radius circle at each location. Each transect consisted of nine fish survey locations that targeted the eastern edge, crest and western edge of each of the three main reef tracts, yet in many cases the nearshore ridge complex (NRC) was mistaken for the Inner and Middle Reefs (Walker et al. *in press*).

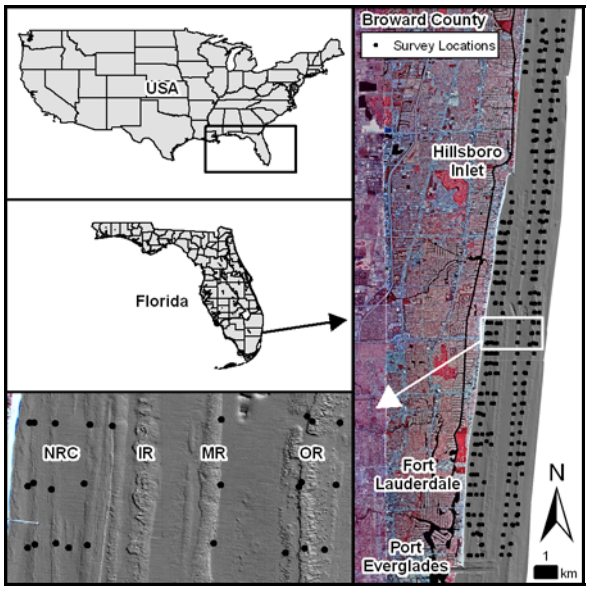

Figure 1. Aerial photo-LIDAR mosaic with the 346 point-count fish assessment sites in northern Broward County, FL, USA. NRC = Nearshore ridge complex; IR=Inner reef; MR=Middle reef; and OR=Outer reef.

GIS topographic analyses of the fish survey locations were performed in ArcGIS 9.2. Triangulated irregular networks (TIN) were created using LIDAR bathymetry for a 7.5 m radius area around each fish survey. This allowed over 12 bathymetric points per area for topographic analyses. The individual TINs were analyzed in 3D Analyst for Z min, Z max, 2D area, 3D surface area, and volume. Elevation was the positive difference between the min and max Z value. The surface rugosity index was the surface area of the TIN divided by its planar area. Volume was calculated as the space between the 3D surface and a horizontal plane at Z min.

Reef fish surveys were categorized by their location in relation to the benthic habitat characterization of Walker et al. (2008). Some habitats were excluded in the prediction model due to low fish survey sample sizes. The benthic habitats used herein were Ridge-Shallow, Colonized Pavement (CP)-Shallow, Linear Reef (LR)-Middle Shallow, LR-Middle Deep, CP-Deep, LR-Outer, and Aggregated Patch Reefs.

Analysis of variance (ANOVA) was used to analyze the data for differences in abundance and number of species per count (i.e., species richness). Abundance data (x) were log transformed using the formula $\log_{10}(x+1)$ to homogenize variance. Tukey HSD *post-hoc* tests were used to determine significance when more than two categories were examined. Linear regression was performed in Statistica 6.0 (Stat Soft Inc.) and an r^2, r, and p-value were reported for a best-fit linear regression line.

Predictions of reef fish abundance and species richness were made based on the linear regression equation of the GIS topographic measurements within each habitat. The model was created at the same scale as the fish surveys. A grid of 15 m square polygons was projected over the entire survey area. Depth, elevation, volume, and surface rugosity index were calculated for each polygon in GIS resulting in each grid polygon having individual topographic statistics and habitat characterization based on its location to the seafloor. The grid polygon topographic data values were then input into the appropriate regression equation based on the GIS metric predictor and its habitat. This generated six columns of prediction data for each grid polygon: a predicted abundance and richness for each of the three GIS metrics.

Results

A comprehensive analysis on how the fish data relate to topographic complexity is presented in Walker et al. *in press*. In summary, both abundance and richness increased with increasing topographic complexity and these relationships changed across the seascape. Richness related to topographic complexity stronger in the shallow habitats, whereas, abundance exhibited a stronger relationship in offshore habitats. *In situ* rugosity measurement yielded the best explanation of fish assemblage structure parameters, but the weaker GIS metric correlations followed similar trends. Since linear regression results varied between habitats and between GIS metrics, a separate regression equation was determined for each. Several of the relationships were not statistically significant but were included in the model for completeness.

The prediction model yielded 134,704 square polygons, each with a value for predicted fish abundance and richness using the elevation, volume, and surface rugosity values generated from the regression equations in their respective habitats, resulting in six separate prediction maps.

Linear regressions of the total measured fish abundance and richness versus the predicted values for all metrics showed statistically significant relationships ($p<0.0001$). Elevation had the highest r^2 values in both abundance and richness of the three GIS metrics, $r^2=0.27$ and 0.39 respectively; surface

rugosity had slightly lower r^2 values than elevation for abundance (r^2=0.25) and richness (r^2=0.38); and volume had the lowest r^2 values for both abundance (r^2=0.19) and richness (r^2=0.31).

ANOVA comparisons of reef fish abundance between the surveys and predictions within habitats showed only one statistical difference where volume abundance was significantly higher than the measured abundance on the LR-Middle Shallow ($p<0.05$) (Fig. 2, upper). In every other case, the predicted means were not significantly different from the measured means for each habitat. This resulted in the data trends of the empirical values emerging in most of the predictions. For example, both measured and predicted reef fish abundance were significantly lower ($p<0.05$) in the CP-Shallow than the LR-Middle Shallow, the LR-Middle Deep, the LR-Outer Reef, and the Aggregated Patch Reef.

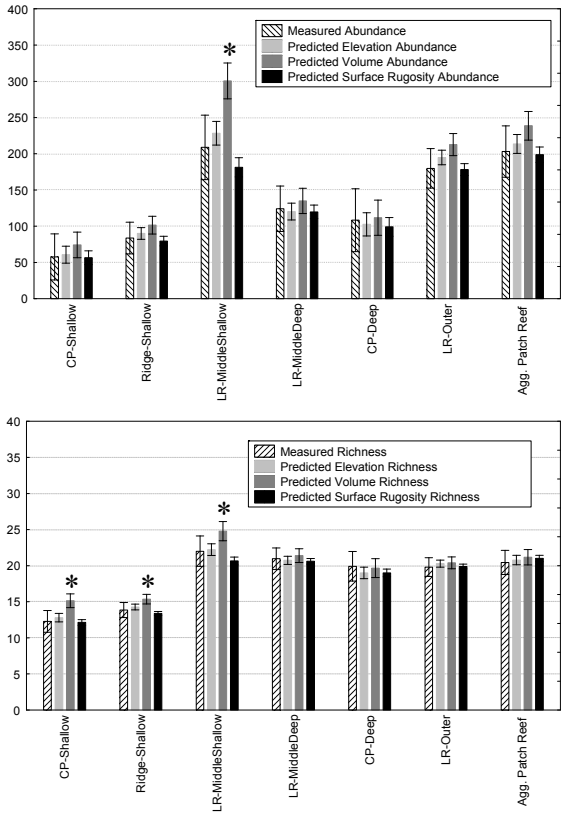

Figure 2. Measured abundance (upper) and species richness (lower) (hashed) and predicted values of reef fish by GIS calculated elevation (light grey), volume (medium grey), and surface rugosity (black) by benthic habitat. Error bars show one standard deviation about the mean. * indicates significant difference from measured abundance ($p<0.05$).

Comparisons of species richness by ANOVA between the surveys and predictions within habitats showed that the predictions did not significantly differ from the measured data with the exception of three significantly higher volume predictions ($p<0.05$) (Fig. 2, lower). In every other case the modeled data showed the same trends between habitats. For example, the CP-Shallow and Ridge-Shallow had significantly lower richness than the other habitats which did not significantly differ from one another for the measured and predicted data ($p<0.05$).

Discussion

Previous analyses of reef fish and LIDAR topography have either not attempted modeling (Kuffner et al. 2007) or focused modeling efforts on species richness (Pittman et al. 2007). The model presented herein adopts an approach to predicting reef fish distribution not previously reported. By using new technologies to project the relationship of both species richness and abundance to large-scale topographic complexity across the seascape, it provides the ability to view, quantify, and relate these predicted data.

Biological modeling involves less certainty than models based on physics or chemistry, which are derived from fundamental laws (Mitasova and Mitas 2002). The accuracy of the model presented herein relies heavily on the observed data. Although statistically relevant, the regressions showed a relatively low agreement between the predicted and measured data (r^2 = 0.27 for abundance and 0.39 for richness). This relationship was expected to be very high ($r^2 > 0.80$) since the model was developed using the same data. The output weaknesses were likely caused by the weak measured relationships between the measured reef fish variables and GIS metrics (Walker et al. *in press*). Because the initial relationship is weak, the output did not yield a high degree of accuracy. However, the comparisons between mean abundance and richness values of the fish surveys (measured data) and the predicted values among benthic habitats showed high agreement. In most of the habitats neither mean predicted abundance nor richness significantly differed from the mean measured values with the exception of volume. Hence, the empirical data patterns between habitats emerged in both predicted abundance and richness exhibiting the same trends in the data within each habitat. This suggests the model is more powerful as a comparative tool than a tool to predict absolute values in an area.

As a comparative tool, the model can provide very useful information for decisions on Marine Protected Area (MPA) placement. An MPA's location is of key importance to optimize its potential (Baker 2000). MPAs representing a full range of habitats are most effective (Carr et al. 2003) and they should contain essential fish habitat (Rieser 2000) and highly rugose areas (Friedlander et al. 2007). This model provides the information necessary to statistically compare different areas based on the organism's relationship to

topography throughout the seascape. For example, a comparison of model data between two 1 km stretches of Middle Reef shows clear quantifiable differences (Figure 3). A T-test comparison showed predicted mean abundance in area A (253.9 ± 4.5 SEM) was significantly higher than area B (178.8 ± 2.7 SEM) and area A contained significantly higher species richness (23.8 ± 0.16 SEM) than area B (21.6 ± 0.09 SEM). In this example, area A would be a better conservation area based on predicted fish data and because these data are in GIS, they can be analyzed in relation to other data relevant to MPA design and implementation.

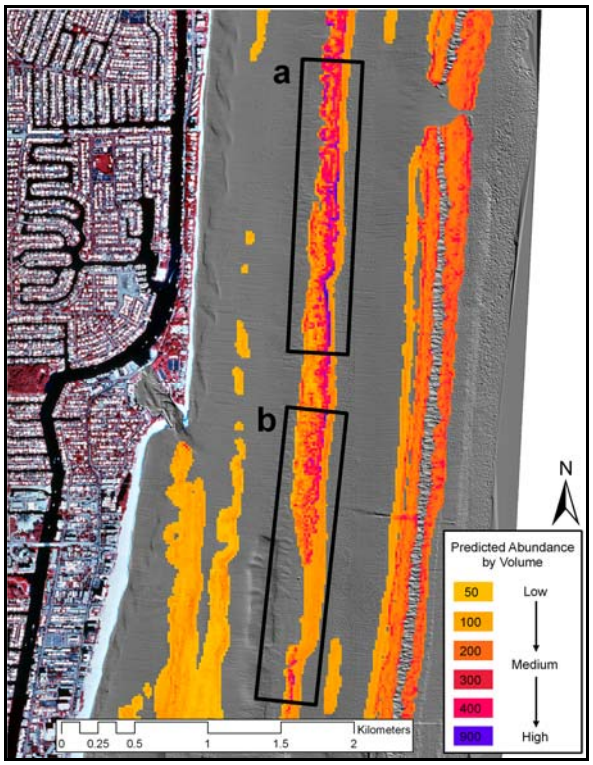

Figure 3. A map of the predicted fish abundance by volume showing two identically-sized areas used for statistical comparison. Box a contains significantly higher mean predicted abundance and richness than box b.

Bathymetry

High resolution bathymetry is some of the most valuable data to acquire in mapping submerged lands. These data, which have many uses beyond the scope of this study, were essential to mapping the benthic habitats and obtaining topographic measurements of discrete areas over the seascape. The 4 m resolution bathymetry was sufficient to map the habitats; however, it was not ideal for measuring the topographic variables at a sufficient operational scale to the fish assemblage (Walker et al. *in press*). Differences in bathymetric resolution have implications on the topographic measurements calculated in the GIS (Wolock and McCabe 2000). It is recommended that future bathymetric surveys be taken at a higher density to obtain more accurate topographic information.

Benthic Habitat Mapping

Benthic habitat mapping is an essential tool for effective management of submerged resources (Friedlander et al. 2007). Mapping the resources not only aids resource managers in the determination of mitigation for impacts, the designation for marine protected areas, and the identification of essential fish habitat, it also can elucidate previously unforeseen relationships in data brought on by the proper classification of the sample sites (Walker et al. *in press*). For Example, on a patch reef system in Biscayne National Park, FL, Kuffner et al. (2007) did not find significant differences between abundance and richness with rugosity in pooled data, but found significance when the data were split by individual patch reef. Hence, measuring changes in relationships between habitats is essential to the accuracy of prediction models.

The scale of habitat mapping can also affect the model and it is likely that a map at a finer scale would produce better results. In the current map, the area within each polygon is homogenous as described by each classifier (Walker et al. 2008). The absence of within-polygon variation might significantly underestimate the total variance of the polygonal data (Bian 1997). The variation of benthic cover within habitats could introduce significant variation in the data, obscuring other relationships (Aaby et al. 2004). Since variations within habitats (patchiness) were acoustically detected (Walker et al. 2008), it is possible that this confounded the reef fish-topographic complexity relationship.

It is recommended that benthic habitat mapping be created at the finest scale possible to include variations of patchiness within major habitat categories. This can be accomplished through high density acoustic surveys or LIDAR backscatter habitat classification (Foster et al. *in press*).

Model Adaptation

This empirical static model has been developed based on the statistical analyses of observed data enabling views of the relationship between reef fishes and their habitats on a large scale (>100 km²), allowing for statistically comparable analyses between areas based on empirical data, and thus giving statistical support to resource management decisions. Its simple design makes it highly adaptable to other uses. The framework can be used to predict any biological/ecological relationship to topographic complexity provided the bathymetry and mapping

data are of the appropriate scale. For example, it could be used to predict coral reef biodiversity via topographic complexity. The grid polygon size could be adjusted to change the scale of the model and the benthic habitat resolution could be tuned accordingly.

This system could also be taken to the next level as a spatial decision support system- a computer-based system designed to assist decision making (Corbett et al. 2002). The framework could be assembled in a user-friendly program with more automated processes and the ability to obtain instant viewable results in a GIS. Once the grid has been created and the topographic statistics calculated, fine tuning the ecological process relationship is a statistical procedure that could be self-contained in a program that would allow a user to specify the relationship (i.e. input the regression equations) and quickly view the results. This could be extremely useful to scientists studying different ecological processes and resource managers in making decisions on resource use and/or mitigation.

Future research can greatly increase this model's accuracy. Increasing the resolution of bathymetric data and habitat mapping units would eliminate several possible error sources; however, research is still needed to better understand the dynamics of how reef fish relate to topographic complexity and the other ecological factors influencing their distributions. Better understandings of the appropriate measurement scale and the scales at which reef fish operate would help to model their distributions more accurately. As these relationships are uncovered, modeling efforts using topographic complexity as a proxy for organism distribution may become more accurate.

Seafloor characterization using multibeam and optical data at French Frigate Shoals, Northwestern Hawaiian Islands

J. Weiss[1], J. Miller[1], J. Rooney[1]

1) Joint Institute for Marine and Atmospheric Research, University of Hawaii, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, and NOAA Coral Reef Ecosystem Division

Abstract. Multibeam bathymetry, backscatter, and optical data collected by the NOAA Coral Reef Ecosystem Division (CRED) were used to create maps of seafloor habitats on the bank top at French Frigate Shoals (FFS) in water depths ranging from <10-100 m. Supervised classification of backscatter and optical data with user-defined classes results in seafloor maps such as hard (rock, rubble, etc.) and soft (sandy) bottom. However, they suffer from a dependence on the generally limited optical data. Uncertainties in camera sled positioning, limited availability of optical data, and user bias in the supervised class definitions suggest an alternate approach may be necessary. Unsupervised classification of different combinations of bathymetry and backscatter derivatives uses the statistical separability of the data to define unique seafloor types. The optical data are then used to define and evaluate the accuracy of the classes. A variety of methods are being evaluated to characterize benthic habitats and the resulting maps are being used to improve sampling techniques for long-term ecosystem monitoring and to guide groundtruthing operations. Future plans include using these methods to identify coral-rich and species specific environments in the Northwestern Hawaiian Islands (NWHI).

Key words: seafloor characterization, multibeam bathymetry, backscatter, Northwestern Hawaiian Islands

Introduction

Since 2002 the NOAA Coral Reef Ecosystem Division (CRED) has collected multibeam bathymetry, backscatter, and optical data as part of an effort to delineate benthic habitats of coral reef ecosystems throughout the U.S. Pacific Islands. The data provide resource managers with high-resolution maps of the seafloor and ground-truth information in water depths greater than 20 m.

Much of the mapping has focused on the islands, banks, and atolls that form the Northwestern Hawaiian Islands (NWHI) (Fig. 1), a long chain of inactive volcanoes produced by a deep seated mantle hotspot currently located beneath Kilauea Volcano (Rooney et al. 2008). Pacific tectonic plate motion slowly carries the volcanoes to the northwest away from the hotspot and they subside and become low-lying islands, atolls, flat-topped banks, and eventually guyots (Grigg 1982). Due to their remote nature, the NWHI are home to some of the healthiest coral reefs in the world and are often referred to as near-pristine coral-reef ecosystems (Page-Albins et al. 2009). It is critical that they are studied to provide baseline information for comparative analyses with degraded reef ecosystems.

Here we present results from recent efforts to create maps of seafloor substrates by applying basic image processing techniques to a combination of multibeam bathymetry, backscatter, bathymetric derivatives, and optical data collected at French Frigate Shoals (FFS) in the NWHI. These efforts have resulted in hard and soft seafloor substrate maps covering the surveyed portion of the FFS bank top. The maps are being used to determine long-term monitoring sites in the framework of a habitat-based, stratified random sampling design (Ault et al. 1999) and for continued coral reef ecosystem research in the NWHI.

Data

Figure 1 shows the bank top bathymetry data collected at FFS in 2005 using hull-mounted multibeam sonars: a 240-kHz Reson 8101 on the 8-m-long survey launch R/V *AHI* (Acoustic Habitat Investigator) and a 300-kHz Kongsberg EM3002d on the NOAA Ship *Hi'ialakai*. Both sonars provide bathymetry and backscatter data logged in the Generic Sensor Format (GSF). Vessel position, velocity, attitude, heading, predicted tides, and sound-velocity corrections are applied to the data in real-time.

The bathymetric data were edited on a swath-by-swath basis and in an area-based editor using SAIC's SABER software. Generic Mapping Tools software (Wessel and Smith 1998) was used to create ASCII grids for import and analysis in ArcGIS. The backscatter data were processed using Hawaii Mapping Research Group (HMRG) software.

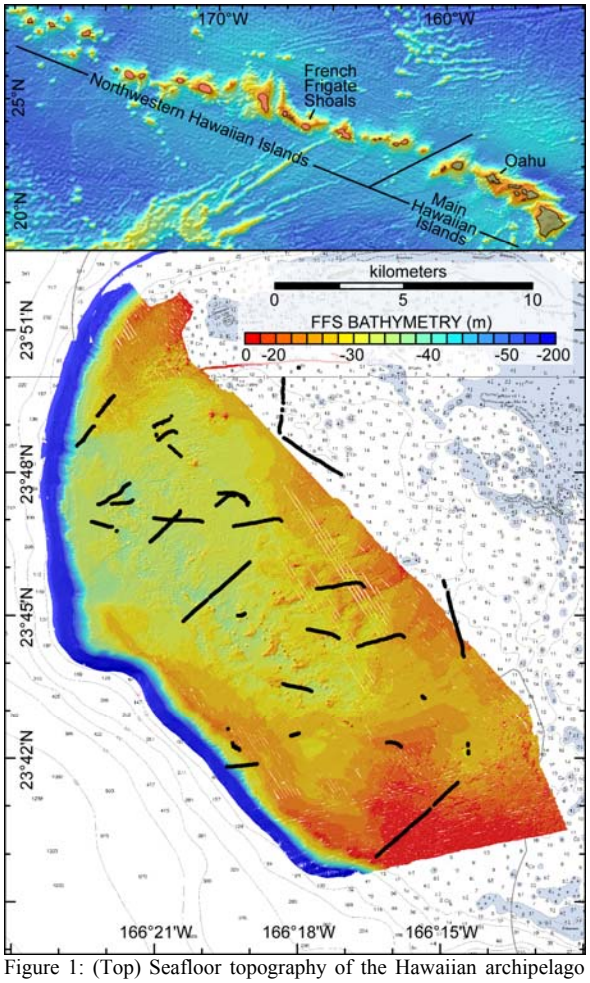

Figure 1: (Top) Seafloor topography of the Hawaiian archipelago derived from satellite altimetry and ship soundings (Smith and Sandwell 1997). The subaerial extents of the MHI and the prominent islands, atolls, banks in the NWHI and the shelves around them are outlined. (Bottom) Multibeam bathymetric data collected by NOAA over of a portion of the bank top at FFS. TOAD tracks are shown in black. The data are overlain on a NOAA NOS nautical chart where shoal depths are colored.

Optical data were collected at FFS from 2001-2005 using the Towed Optical Assessment Device (TOAD) and were analyzed according to the CRED classification scheme (www.soest.hawaii.edu/pibhmc) that includes factors such as substrate type, living growth on the seafloor, geomorphic zone, and the size and abundance of holes in the substrate.

Methods

Initially we took a qualitative approach to seafloor characterization by visually comparing the data. For example, we related backscatter intensity and seafloor slope to the substrate type, as determined by the optical data, by observing that hard (rock, rubble) and coral-rich substrate correspond to high backscatter intensity and slope, while soft (sandy) substrate correspond to lower backscatter intensity and slope.

However, coral-reef and fisheries managers generally have little experience in interpreting optical and acoustic datasets to form management and monitoring plans. They stated the need for integrated map products and in particular the NWHI Papahaʻnaumokuaʻkea Marine National Monument (NWHIMNM) managers requested maps showing areas of hard and soft seafloor substrate that could be used in the framework of a habitat-based, stratified random sampling design (Ault et al. 1999). To accomplish this goal we took an image processing approach using the ENVI software package commonly used to analyze satellite imagery by the remote sensing and planetary science communities.

Acoustic backscatter data are the most useful dataset available for FFS for identifying hard and soft seafloor. Initially a supervised classification technique, which clusters pixels into pre-defined classes, was applied to the data. Region of interest (ROI) classes were chosen by querying TOAD data based on photos that were classified as either ≥80% hard bottom or ≥80% soft bottom (Fig. 2).

A 2-class maximum likelihood supervised classification algorithm was run on ENVI software using the 2 ROI classes and a 3-band image containing backscatter and small- and large-scale bathymetric variance. Variance, derived from the bathymetric data, is the square of the standard deviation of a pre-defined number of neighboring pixel cells. Variance calculations were performed using ArcGIS Spatial Analyst tools. Small-scale variance, calculated for a 3x3 pixel cell neighborhood, is useful for defining topographic features such as sediment ripples or possible coral-rich regions, whereas the large-scale variance, calculated for a 5x5 neighborhood, is useful for defining seafloor ridges, pinnacles, and significant changes in slope. Variance proved to be a useful bathymetric derivative in previous efforts to map seafloor habitats by Dartnell and Gardner (2004) and including both the small- and large-scale variance in our analyses generally gave better results despite their visual similarity (Fig. 3). The acoustic data were resampled to a 5 m grid cell size prior to running the ENVI analyses. Additionally, the Reson 8101 and Kongsberg EM3002D datasets were processed separately due to their different frequency contents and the resulting classified images were combined during post-processing.

Initial results from the supervised classification were unsatisfactory because obvious artifacts around data gaps were apparent. There was also concern that the technique relied too heavily on the optical data. Uncertainties in camera sled positioning, absence or limited availability of optical data for many areas, and bias in the supervised class definitions made it necessary to investigate an alternative approach.

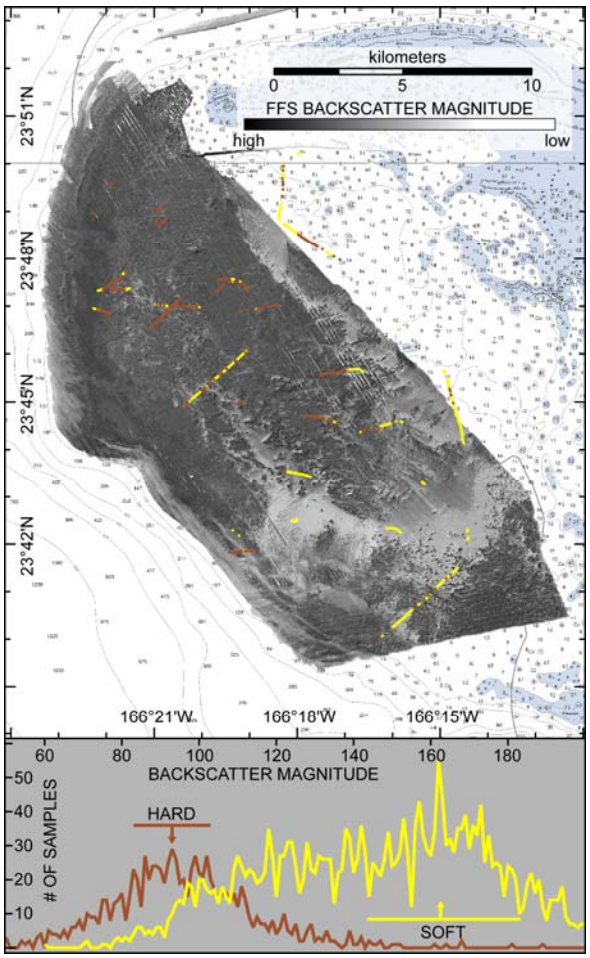

Figure 2: (Top) Backscatter imagery and TOAD tracks colored yellow for ≥80% sand/soft bottom and brown for ≥80% hard/rock bottom. (Bottom) Backscatter magnitude vs. number of samples for hard (brown) and soft (yellow) seafloor ROI's. Lower backscatter values are harder bottom due to the reversed polarity dataset used to extract the backscatter magnitude values for the plot. Vertical arrows and horizontal bars indicate the mean and standard deviation for each ROI respectively.

Consequently an unsupervised classification technique was chosen, which relies only on the data statistics. Using this technique, no user defined training classes or inputs other than the acoustic data are required for creating the classified image. After testing different combinations of input data and various classification algorithms a 2-class K-Means unsupervised classification algorithm was run on ENVI software using a 4-band image containing backscatter, bathymetric rugosity, and small- and large-scale bathymetric variance (Fig. 3) to derive regions of hard and soft substrate for the mapped portion of the bank top. Rugosity is calculated using the Benthic Terrain Modeler in ArcGIS (Jenness 2003). The unsupervised classification algorithm calculates class means evenly distributed in the data space and then iteratively clusters the pixels into the nearest class using a minimum distance technique. In general, the unsupervised classification dealt better with data gaps and delineation of isolated hard bottom areas surrounded by sand, such as pinnacles, than did the supervised technique. The hard and soft classes were assigned to the resulting unsupervised image by visually comparing the optical data with the classified image.

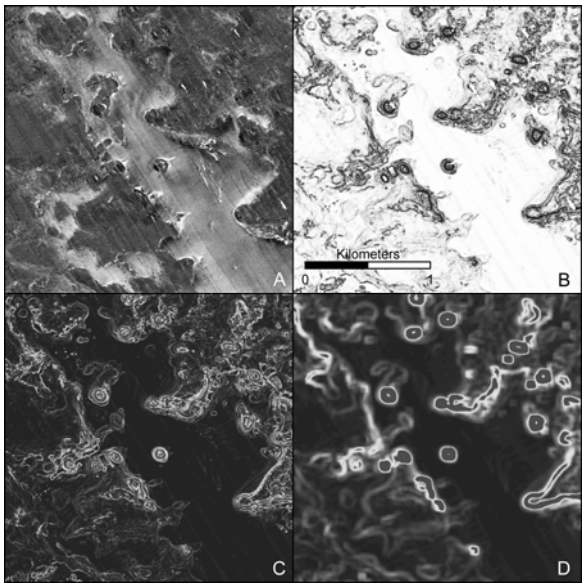

Figure 3: (A) Backscatter, (B) bathymetric rugosity, (C) small-scale bathymetric variance, and (D) large-scale bathymetric variance for a small subset of the FFS bank top. Note the 1-km-long scale bar in (B). Higher backscatter is indicated by darker colors in (A), higher rugosity is indicated by darker colors in (B), and higher variance is indicated by lighter colors in (C, D).

Results and Conclusions

Figure 4 shows the hard and soft seafloor substrate map created using the unsupervised classification technique for a portion of the bank top at FFS. A confusion matrix was calculated to compare the classification results with the ground truth (TOAD) data. The overall accuracy of the classification results when compared to the user-defined ROI classes is ~80% but the accuracy is much less (~30%) when the results are compared with the entire TOAD dataset. This difference is most likely associated with the positional uncertainties of the TOAD data and errors in the unsupervised classification and suggests that visual comparison of the classification results with the optical data is imperative for assigning substrate types to classes. Subsequent optical and SCUBA-based ground truth operations at FFS suggest the ~80% accuracy is a realistic overall assessment of the unsupervised classification results.

Substrate maps, produced as describe above, are currently being used by NWHIMNM scientists and managers to determine long term monitoring sites. It appears that this is an appropriate approach for

integrating high-resolution multibeam survey datasets covering large areas with limited coverage optical datasets. This method can easily be expanded if high quality acoustic and optical data are available, it has been applied to a number of other areas, and the resulting maps and data are available for download at www.soest.hawaii.edu/pibhmc. The processing approach described above and error assessment techniques continue to be refined to create accurate seafloor substrate maps.

CRED study sites span the tropical Pacific Ocean basin and data acquisition is often limited by the amount of time available to survey in remote locations. This can result in maps covering a wide area with sparse coverage and some data gaps. The NOAA Biogeography Branch is applying similar image processing techniques to create spatially limited seafloor substrate maps with dense coverage and few data gaps around islands in the Caribbean, such as Puerto Rico (Costa et al. 2008). However, the specific method described here has been developed to meet needs of resource managers in coral reef ecosystems with somewhat sparse multibeam and minimal optical data.

Although logistical constraints may limit the coverage of acoustic datasets (multibeam and backscatter), experience has demonstrated the importance of designing surveys to collect high quality backscatter data. Greater coverage can be attained by concentrating only on maximizing data collection. However, the slower survey speeds and other constraints that may be required to collect high quality backscatter data have been found to be justified because it is undoubtedly the best discriminator of hard and soft seafloor. Additionally, dense grids of optical ground truth data aid tremendously in class determination, derived layer validation, and error assessment.

The coral reef community has only begun to apply image processing techniques (e.g. Dartnell and Gardner 2004; Blondel and Sichi 2008; Marsh and Brown 2008) to acoustic and optical datasets for habitat classification and characterization. These methods represent emerging techniques with much broader characterization and predictive possibilities. For example, predictive habitat mapping (Pittman et al. 2007) expands the utility of acoustic and biologic datasets to predict biomass and fish species abundances based on marine organism seafloor habitat preferences.

Comparing Semi-Automated Methods for Classifying Multibeam SoNAR & Airborne LiDAR Imagery

B. Costa[1] and T. Battista[1]

1) NOAA Biogeography Branch, 1305 East West Highway, N-SCI-1 SSMC 4, Silver Spring, MD 20910, U.S.A.

Abstract. Benthic habitat mapping supports ecosystem-based management objectives by contributing to the development of detailed species utilization models, which link physical habitats to biological information. Shallow to deep-water marine habitats have been successfully characterized by manually digitizing and attributing optical and acoustic remotely sensed imagery. These resulting maps, while extremely useful, are subjective and ultimately irreproducible because they depend on the accuracy and interpretation of the person that is digitizing. Here, we semi-automate the seafloor feature extraction and classification process of high-resolution multibeam (MBES) sound navigation and ranging (SoNAR) and light detection and ranging (LiDAR) imagery using three classification techniques—Support Vector Machines (SVM), Classification & Regression Trees (DTC) and Object-based Segmentation (OBS). The ability and accuracy of these three techniques to delineate and characterize seafloor features was qualitatively compared at relevant spatial and thematic scales using georeferenced underwater imagery. Overall, we found that DTC and OBS out-performed SVM, as these two methods produced habitat maps that were qualitatively more accurate. This analysis suggests that DTC and OBS have the potential to help scientists more quickly and objectively characterize the seafloor, allowing resource managers to better assess the changing health of coral reef ecosystems.

Key words: LiDAR, multibeam SoNAR, MBES, coral reef ecosystems, benthic habitat mapping

Introduction

Benthic habitat mapping supports ecosystem-based management objectives by contributing to the development of detailed species utilization models, which link physical habitats to biological information (Friedlander and Parrish 1998; Pittman et al. 2007). Shallow to deep-water marine habitats have been successfully characterized by manually digitizing and attributing optical and acoustic remotely sensed imagery (Kendall et al. 2005; Battista et al. 2006). These resulting maps, while extremely useful, are subjective and ultimately irreproducible because they depend on the accuracy and interpretation of the person that is digitizing.

In the following study, we address this problem of subjectivity by semi-automating the seafloor feature extraction and classification process of high-resolution MBES and LiDAR imagery using three separate classification techniques. These three techniques—SVM, DTC and OBS—are fundamentally different in how they partition an image into separate classes.

SVM separates an image into classes by maximizing the margin between two groups of pixels in *n*-dimensional space (Vapnik et al. 1997). This margin is delineated using two parallel hyperplanes. The points nearest to these hyperplanes are called support vectors.

DTC separates an image into classes using binary recursive partitioning (Breiman et al. 1984), which is an iterative process whereby image pixels are split into two groups that are as homogenous as possible. The process continues until no more useful splits are found.

OBS separates an image into classes using edge detection algorithms (Haralick 1979; Blaschke et al. 2000). These algorithms detect the boundaries of homogenous groups of pixels. The pixels within each group are similar to each other based on a combination of characteristics, such as intensity and texture.

Given the methodological differences, we qualitatively compared these techniques to determine which was the most accurate,

efficient and robust method for semi-automating the feature extraction and classification process. In doing so, we addressed the following key research questions:

(1) Which of these classification techniques most accurately delineated biologically & geomorphologically relevant habitats in Abrir La Sierra Conservation District?

(2) What are the strengths and weaknesses associated with each semi-automated classification technique?

Materials and Methods

Description of Study Site

The study site, Abrir La Sierra Conservation District, is a marine protected area (MPA) that is located 20 km off the western coast of Puerto Rico. This 16.7 km^2 region was designated as an MPA in 1996 due to concerns over declining reef fish populations (Waddell and Clark eds. 2008). The economically important species, red hind (*Epinephelus guttatus)*, was of particular concern because it uses Abrir La Sierra as a spawning aggregation site (SPAG). SPAGs are crucial to the ecology of an area because they help replenish fish populations, keeping their numbers relatively stable year after year. Since these aggregation sites are so vital, a concerted effort has been made to better understand them by mapping and monitoring changes in their associated benthic habitats.

Data Acquisition: System Specifications

Bathymetry and intensity imagery were acquired for the Abrir La Sierra using MBES and LiDAR. "Bathymetry" denotes the depth of the seafloor and was calculated by measuring the time required for an individual pulse of light or sound to travel from the sensor to the seafloor and back again. "Intensity" denotes the amount of light or sound that was scattered back to and recorded by the sensor. Data from both sensors were collected and processed to meet the International Hydrographic Organization Order 1 horizontal and vertical accuracy standards.

LiDAR data were acquired between 4/7 and 5/15/2006 for elevations between 19 m above sea level down to 50 m below sea level using a Laser Airborne Depth Sounder (LADS) Mk II Airborne System. This airborne system uses a 900 Hz neodymium-doped yttrium aluminum garnet laser, which is split by an optical coupler into an infrared (1064 nm) beam and a green (532 nm) beam. The infrared beam measures the datum height at nadir, and the green beam oscillates across-track to measure depths and/or elevations. The airborne survey was flown at altitudes between 1,200 and 2,200 ft. The raw data were logged using the Tenix LADS Airborne System and were converted using the LADS Mk II Ground System. The soundings were referenced to the NAD83 UTM 19 N horizontal coordinate system and to the Mean Lower Low Water (MLLW) vertical coordinate system (Stephenson and Sinclair 2006).

MBES data were acquired between 4/14 and 4/24/2007 for depths between 21 and 290 m using a Simrad 1002 (95 kHz) MBES. This hull-mounted, ship-board system has 111 electronically stabilized beams with 2° widths, rectilinearly arrayed 75° to the port and starboard of nadir. It achieves seafloor coverage of 7x water depth down to 1,000 m. The vessel's positioning and orientation were determined by the Applanix POS/MV 320 V4. The data parcels were logged using Kongsberg's MERLIN v5.2.2 acquisition and control program, and were referenced to the NAD83 UTM 19 N horizontal coordinate system and to the MLLW vertical coordinate system (Battista and Stecher 2007).

The LiDAR bathymetry and intensity surfaces were created at 4x4 and 5x5 m spatial resolutions (respectively) using CARIS Base Editor v2.0 software. The MBES bathymetry and intensity surfaces were processed and created at 5x5 and 1x1 m spatial resolutions (respectively) using CARIS Hips & SIPS v6.0 and Geocoder v3.2.1 software (Fonseca and Calder 2005). Both the LiDAR bathymetry and the MBES intensity surfaces were resampled to 5x5 m resolutions. All of the surfaces were exported as GeoTiffs and ingested into ArcGIS 9.2 for further analysis.

Ground Validation: Underwater Video Data

Georeferenced imagery of the seafloor was collected using NOAA Biogeography Branch's drop camera system between 4/14 and 4/24/2007. This system is equipped with lights, scaling lasers, an acoustic transponder, a digital video camera and a high resolution still camera (ccma.nos.noaa.gov/products/biogeography/usvi_nps/camera.html). The integration of these components allows for the collection of highly resolved and spatially accurate underwater imagery.

Each suitable, underwater image was visually interpreted and attributed by a trained observer using a hierarchical habitat classification scheme. This scheme defined broad and fine-scale benthic habitats on the basis of 13 geographic zones, 12 unique geomorphological structure types and 4 unique biological cover types using a variable minimum mapping unit (www8.nos.noaa.gov/bhv/bhvMapBrowser.aspx). The broad structure types included algal nodule pavement, bedrock, mud, pavement, sand and scattered coral and rock. The cover types included coral, macroalgae, turf and uncolonized. The resulting classified images were used to train the machine learning algorithms and to qualitatively validate the preliminary habitat classifications. A robust, quantitative accuracy assessment was not conducted because there were insufficient numbers of independent points (> 25) per unique thematic habitat class.

Data Processing: Surface Creation & Selection

A suite of metrics describing the complexity of the seafloor was created from the LiDAR and MBES bathymetric surfaces to aid in the identification and classification of benthic habitats. These morphometrics included: standard deviation of water depth, rugosity, slope, curvature & fractal dimensions (Table 1).

Each of these metrics were re-calculated at a range of spatial scales (10, 30, 50 & 75 m radii) using a median, circular moving window in ArcGIS 9.2. This multi-resolution approach was taken because fish and corals respond to benthic habitats at varying spatial scales (Kendal et al. 2003; Pittman et al. in press). These different metrics were then stacked in ENVI 4.4, creating a single composite image for each data type at each spatial scale (Fig. 1). The principal components of these composite images were calculated to determine the degree of correlation between pairs of metrics. The least correlated metrics were then included in the semi-automated classification.

Morphometric	Unit	Description	Analytical Tool
Standard deviation (SD) of water depth	Meters	Dispersion of water depth values about the mean	Focal statistic in ArcGIS Spatial Analyst
Rugosity	Ratio value	Ratio of surface area to planar area	Benthic Terrain Mapper toolbox (Jenness, 2002)
Slope	Degrees	Maximum rate of change in slope between cell and eight neighbors	ArcGIS Spatial Analyst's slope function
Curvature	1/100 z units	Rate of change in curvature across the surface highlighting ridges, crests and valleys	Curvature function in ArcGIS 3D Analyst
Fractal dimension (*D*)	Unitless	A measure of surface roughness with values between 2 and 3	FocalD script in LandSerf 2.2 (Wood, 2005)

Table 1. Description of morphometrics used to characterize and classify the homogenous habitats on the seafloor.

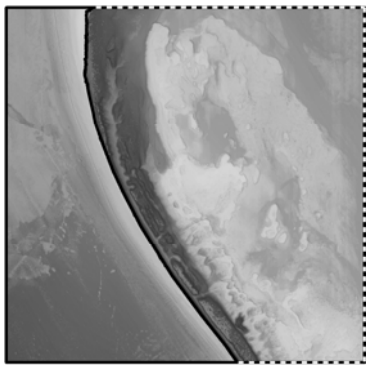

Figure 1. These composite images depict intensity, depth and slope surfaces as individual RGB bands. The imagery outlined by the black line (left) was acquired using MBES. The imagery outlined by the dashed line (right) was acquired using LiDAR.

Comparing Classification Methods

Several steps were needed to classify these composite images. The first step was to create regions of interest (ROIs) using the classified, video imagery. These ROIs were used to train each of the machine learning algorithms, which were subsequently deployed in ENVI original and ENVI Zoom v4.4. After each algorithm was run initially, the resulting outputs were refined by incrementally adjusting key input parameters. It was, however, difficult to objectively determine if these parameters were

optimized without being able to conduct a quantitative accuracy assessment. Such an assessment should be conducted in the future, allowing for the explicit optimization of these parameters.

The final step in this process was to visually compare the outputs from the three different methods to determine their qualitative accuracy. Surfaces with "high" qualitative accuracy: (1) did not confuse one habitat type with another; (2) did not identify geometric or radiometric artifacts in imagery as habitat features; (3) were capable of detecting subtle spectral differences between habitat types in the imagery; and (4) were capable of concurrently delineating fine and coarse-scale habitat features (e.g., individual patch reefs and aggregate patch reefs). Surfaces with lower qualitative accuracy did not meet one or all of these criteria.

Results

Classification Accuracy of LiDAR Imagery

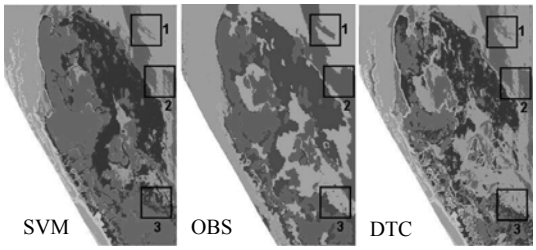

Figure 2. The final classified surfaces developed from the LiDAR imagery using SVM (left), OBS (middle) and DTC (right). Areas 1, 2 and 3 denote locations where the classified results did not meet one or several of the qualitative accuracy criteria as outlined above.

The three different machine learning techniques produced noticeably different classification results when applied to the LiDAR imagery. Overall, DTC produced (qualitatively) the most accurate result of the three methods. SVM and OBS produced less accurate results for two primary reasons: (1) they consistently confused one habitat class (sand) with another habitat class (low rugosity pavement) (Fig. 2, Area 1); and (2) they did not identify and extract many fine-scale features (reef holes) in the imagery (Fig. 2, Area 3). Despite DTC having produced a more accurate result, OBS was more resilient to geometric or radiometric artifacts in the imagery, and was less likely to identify them as habitat features (Fig. 2, Area 2).

Classification Accuracy of MBES Imagery

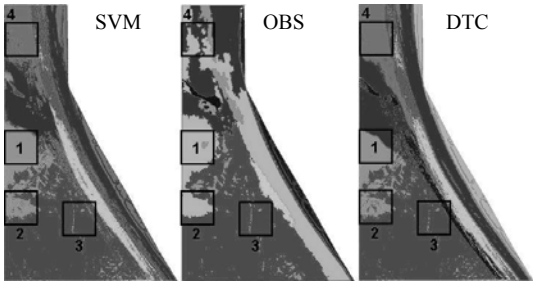

Figure 3. The final classified surfaces developed from the MBES imagery using SVM (left), OBS (middle) and DTC (right). Areas 1, 2, 3 and 4 denote locations where the classified results did not meet one or several of the qualitative accuracy criteria as outlined above.

The three different machine learning techniques also produced noticeably different classification results when applied to the MBES imagery. Overall, OBS produced qualitatively the most accurate result out of the three methods. SVM and DTC produced less accurate results for three primary reasons: (1) they consistently confused one habitat class (i.e., pavement) with another habitat class (i.e., bedrock) (Fig. 3, Area 1); (2) they consistently identified geometric or radiometric artifacts in the imagery as bona fide habitat features (Fig. 3, Area 2); and (3) they failed to detect subtle spectral differences between habitat types in the imagery (Fig. 3, Area 4). All three methods adequately extracted both fine and coarse-scale features simultaneously (Fig. 3, Area 3).

Discussion

A qualitative analysis of the three semi-automated techniques and their final, classified outputs revealed that each technique had specific strengths and weaknesses. These strengths and weaknesses were most likely the combined result of the algorithm's input parameters, the different spatial resolutions of the MBES and LiDAR surfaces, the shape of the re-scaling kernel, and the correlation between surface metrics. Changes to any of these parameters could have altered the classification results.

That being said, overall, DTC outperformed the other methods when applied to imagery with spectrally distinct habitats, and to imagery with few geometric or radiometric artifacts. It was also the fastest of the three methods, as it took the least amount of time to produce an

accurate, classified image. OBS, on the other hand, was the slowest of the three techniques, albeit it did outperform the other methods when applied to imagery that had geometric or radiometric artifacts and to imagery that had habitats with similar spectral signatures. Overall, DTC and OBS both outperformed SVM because their surfaces had higher qualitative accuracies. SVM was most likely outperformed because it had many more parameters to adjust and optimize than did the two other methods.

A final benthic habitat map was created using the DTC surface developed from the LiDAR imagery and the OBS surface developed from the MBES imagery (Fig. 4). This seamless map characterized 18 unique seafloor habitats in 10 to 290 m of water.

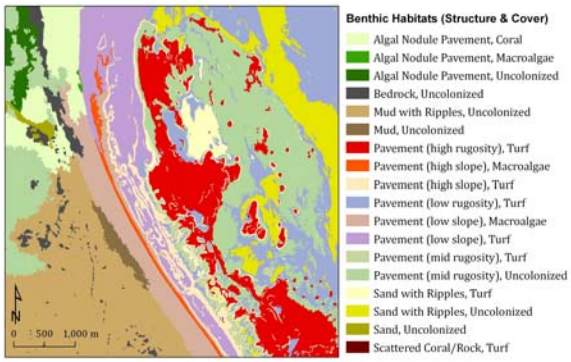

Figure 4. This graphic depicts the final, seamless benthic habitat map of Abrir La Sierra Conservation District. It was created by merging and edge matching the best classification outputs developed from the LiDAR and MBES imagery.

In conclusion, our current data and analysis indicate that DTC and OBS have the potential to help scientists create benthic habitat maps more quickly and efficiently. Future analysis (and a quantitative accuracy assessment) will improve this process further by objectively determining the optimal algorithm parameters. Hybridizing the OBS and DTC methods may also contribute to this improvement by integrating of the strengths of both techniques. The accuracy, objectivity and repeatability of habitat mapping will allow resource managers to more frequently and reliably assess the changing distribution (and ultimately, health) of the coral reef systems that they manage. Improving our understanding of these ecosystems is the key to identifying and mitigating the heterogeneous threats that face these important and precious resources.

Acknowledgements

The authors would like to thank Charlie Menza for processing and classifying the underwater photography. Also, special thanks to NOAA's Coral Reef Conservation Program for their continued support of the Biogeography Branch's effort to characterize coral reef ecosystems in the U.S. Caribbean.

Assessing the distribution of patch reef morphologies in the Lower Florida Keys, USA, using IKONOS satellite imagery

Abstract. As live coral cover continues to decline in the Florida Keys, it becomes increasingly important not only to determine the location and abundance of live coral remaining, but also to understand why certain areas possess higher coral cover than others. At present, coral cover tends to be highest at shallow inshore patch reefs. Our study has two objectives: 1) to determine, to the full extent visible by satellite imagery, the number and characteristics of patch reefs that could be recognized using IKONOS imagery; and 2) to test the assumption that various morphological groups of patch reefs occupy distinct cross-shelf zones in the Lower Keys. Two previous survey efforts using aerial imagery and reported 420 and 750 patch reefs, respectively, from Big Pine to the Marquesas Keys. By performing a visual assessment on IKONOS satellite imagery, we were able to delineate 2,251 patch reefs for this region. These patch reefs vary in their overall morphology (i.e., shape) and are spatially distributed in several cross-shelf bands. Patch reef classes identified were Aggregate, Atom, Colony, Crescent and Dome. Aggregate patch reefs are very numerous, relatively small, and dominantly located either shallow-midshelf or offshore. Dome, Colony and Crescent patch reefs are larger in area and are most common in the shallow-midshelf or offshore zones. This study represents an important first step in understanding the factors that may be controlling the distribution and shape of patch reefs along the Florida Keys Reef Tract and, subsequently, relating this to living coral cover on modern reefs.

Key words: Florida Keys, patch reef, morphology, coral, remote sensing.

Introduction

Declines in overall live coral cover throughout the Florida Keys are well documented (Porter et al. 2002). The Florida Keys Coral Reef Evaluation and Monitoring Project (CREMP) has monitored 40 reef sites throughout the Keys since 1996. In 2005, coral cover on patch reefs averaged 14.6%, compared to 3.0% for the offshore bank reefs (Beaver et al. 2006). Coral cover has continued to decline on the offshore bank reefs so that live coral assemblages are now concentrated on shallow-water patch reefs. Thus, to adequately assess and protect remaining coral assemblages, it is essential to know the number, extent and spatial characteristics of the many patch reefs spread throughout the region.

The Florida Keys have historically been separated into three geographic regions: Upper, Middle and Lower Keys (Ogden et al. 1994). Previous efforts to determine the number of patch reefs in the Lower Keys utilized aerial survey methods. Marszalek et al. (1977) identified 420 reef structures from Big Pine to the Marquesas Keys. The Florida Marine Research Institute's Benthic Habitat Map of the Florida Keys estimated 750 patch reefs (inclusive of aggregate patch reefs) in the Lower Keys region (FMRI 2000).

Our study area encompasses a 523 km^2 region stretching from Big Pine Key in the northeast to Sand Key Reef in the southwest, and extends from the land to the outer reef system (depth≈20m) (Fig. 1). We used high spatial resolution, georeferenced IKONOS satellite imagery provided by the National Oceanic and Atmospheric Administration (NOAA) to find, categorize and map the size, shape and distribution of patch reefs. Initial observations indicated that patch reef distribution is non-random. Patch reefs appear to occur in distinct bands that parallel land, each with increasing distance from shore. There also appears to be segregation between patch reef morphologies (i.e., shape), with different types rarely sharing a given zone. The goals of this study were to 1) determine the number and characteristics of patch reefs that could be visually identified using IKONOS imagery and 2) test the assumption that various morphological groups of patch reefs occupy distinct cross-shelf zones in the Lower Keys.

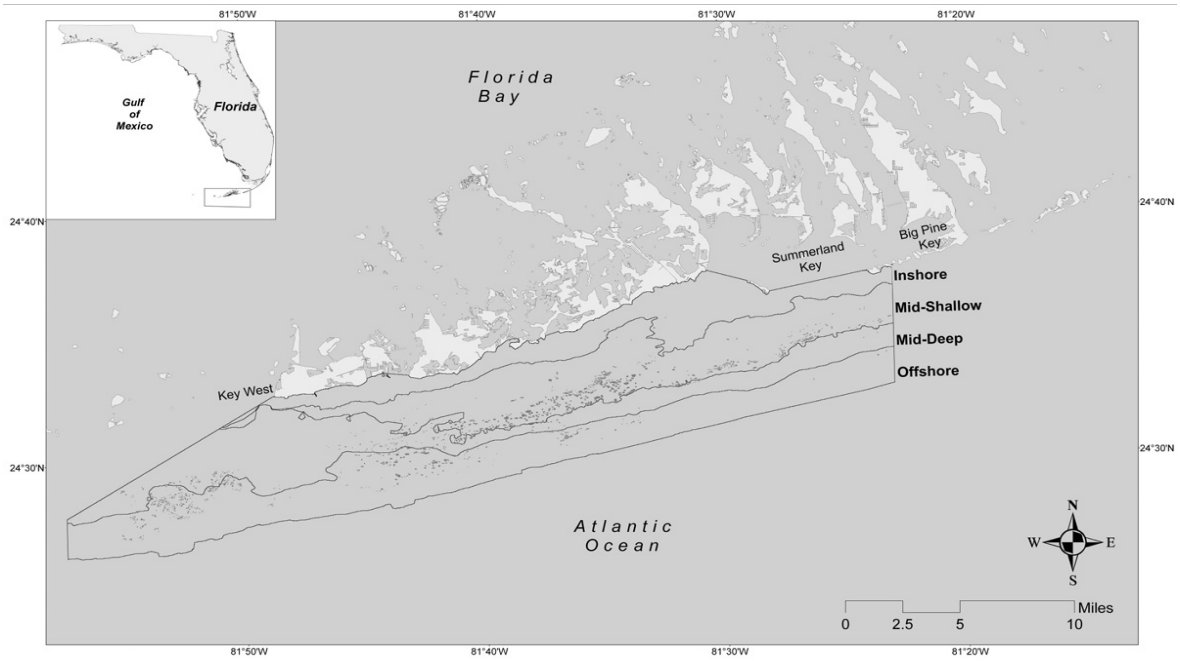

Figure 1: Lower Florida Keys study region displaying cross-shelf zones and patch reef distribution.

Methods

Data Source

Twenty-five IKONOS images acquired during 2006 and corresponding to the Lower Keys region were provided by NOAA. Of these, the four clearest images that provided complete coverage of the study region were selected for analysis, while the remaining 21 images were used to assist in later verification. IKONOS is a privately owned satellite (GeoEye) with a spatial resolution of 4 m that collects data in three visible wavelength bands (450 – 520 nm, 510 – 600 nm and 630 – 700 nm). The Lower Keys were segmented into four zones (Inshore, Mid-Shallow, Mid-Deep and Offshore) using digital bathymetry and clearly visible cross-shelf habitat breaks (Fig. 1). Digital bathymetry was compiled from three sources; NOAA Geophysical Data System (GEODAS), the Benthic Habitat map of the Florida Keys and an internal FWRI bathymetric dataset (Palandro et al. 2008).

Patch Reef Mapping/ Typology

The location of each patch reef was determined by visually examining each image. Cosmetic stretching was applied to the red, green, and blue bands (RGB) to enhance differences between suspected patch reefs and other benthic habitats. When a patch reef was found, it was marked as a point using ENVI 4.3 ® remote sensing software. The decision to classify a structure in the imagery as a patch reef was based on the appearance of a reef-like structure, surrounding benthic attributes (e.g., halo) and local knowledge.

The shape of each patch reef was delineated from the satellite imagery (Fig. 2) using all available overlapping imagery for a given area. The two to three clearest images (e.g. cloud-free, transparent water) were used to verify the presence of a patch reef. After the initial mapping of all visible patch reefs, the designation of each was further confirmed using ancillary datasets. These included satellite imagery, analog aerial imagery and interferometric acoustic data, as well as consulting with people familiar with the area. Final quality control measures for the dataset are still underway; therefore, for the purpose of this study, it is assumed that all reef structures identified in the imagery are in fact patch reefs.

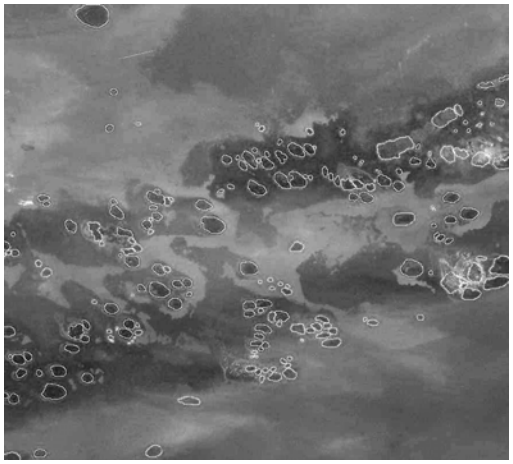

Figure 2: Examples of patch reefs delineated from IKONOS imagery. White versus gray outlines were used to differentiate between reefs during quality control analyses.

After determining the point location of each patch reef, a polygon was created of the entire reef area; the area contained within, and excluding, a visible sand halo. A sand halo is an area that generally fringes a patch reef and is created by grazing herbivores (Randall 1965, Ogden et al. 1973). The bright reflectance of the sand halo is in contrast to the darker return of the actual patch reef (contained within it) and provides a clear boundary for delineating only the reef area. The polygons that were created were exported to ArcGIS 9.3. Patch reef morphology in the Florida Keys has historically been divided into just two categories: dome and linear (Marszalek et al. 1977, Chiappone 1996). Patch reef morphology were classified here into a greater number of morphologies: Aggregate, Atom, Colony, Crescent and Dome (Fig. 3). Each of these morphologies can be considered a subset of the original 'dome' classification.

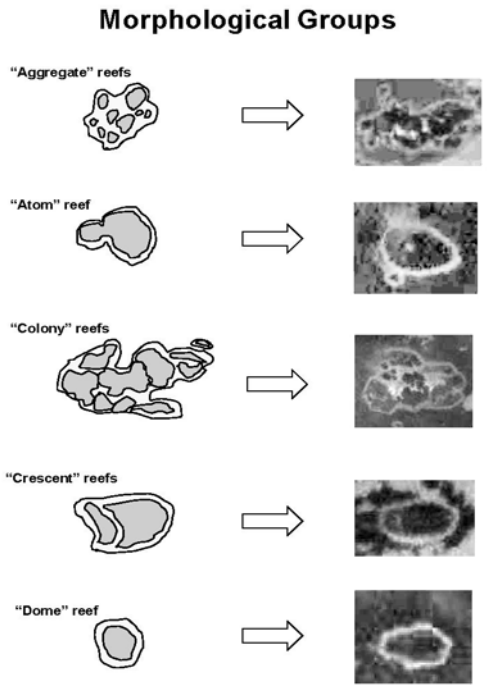

Figure 3: Categories of patch reefs identified.

Defining characteristics of each patch reef morphology are as follows:

Aggregate: a grouping of patch reefs of various sizes - generally three to ten in number – that share a common halo and exhibit complete separation between individual reefs.

Atom: a circular or elliptical-shaped patch reef containing a second patch reef within its sand halo. The secondary patch reef is always many times smaller in scale and is contained completely within the halo of the 'parent' reef, such that it appears in the process of budding off.

Colony: like Aggregate patch reefs, Colony reefs are found in close proximity to one another and share a common halo. Unlike Aggregate reefs they exhibit a 'conjoined' structure, for which a visible sand halo does not entirely separate individual reefs within the group.

Crescent: two patch reefs that share a single halo surrounding their exterior, and have complete separation in between via a sand channel. Crescent reefs always orient themselves in a northeast-southwest direction with the larger of the two reefs shaped like a 'bullet' with the smaller, 'boomerang-shaped' reef trailing in its wake.

Dome: the 'classic' dome patch reef; a single circular or ellipsoid reef with a single halo.

Patch Reef Metrics

Area and perimeter measurements (m^2 and m respectively) were obtained using XTools Pro for ArcGIS 9.3. The major axis of each patch reef was determined by placing a minimum area bounding rectangle around the delineated patch reef polygon. The major (long) axis of the rectangle then served as an estimate of the maximum diameter of the patch reef.

The complexity of each patch was defined by its perimeter to area ratio (P/A). Because this measure is sensitive to the size of the patch reef, a corrected perimeter to area ratio (PAC) was used that is not sensitive to changes in size of a patch of given shape. PAC index values range from 1.0 for a circle, 1.1 for a square, and can become infinitely large for long, narrow, and highly convoluted shapes (Baker and Cai 1992). PAC is defined as,

$$PAC = P / \sqrt{(4\pi \times A)},$$

where P is the perimeter of the individual patch reef polygon and A is the area contained within the sand halo. The PAC index was calculated for each polygon individually and then averaged across the morphological group.

The coastline of the Lower Keys was delineated as a polyline in ENVI and exported into ArcGIS. Distance from shore was derived as a linear measurement between the centroid of each patch reef polygon and the nearest point on the shore. The extreme south-western end of the shoreline defined by this study was Key West. Therefore, the shoreline value used for the patch reefs just inshore of Sand Key Reef would have been Key West. However, the distance from shore measurement for patch reefs west of Key West is greater than if the shoreline had been artificially extended westward toward the Marquesas. For our study, we used only the current land-sea boundary extending from the northern tip of Big Pine Key, to the western end of Key West, as our shoreline.

Table 1: Total number (N), Percent of Each Morphology by Number, Total Area (km^2), Percent of Each Morphology by Area, μ Area (m^2) and Area σ, μ PAC, μ Maximum Diameter (m) and Maximum Diameter σ (m), μ Distance to Shore (km) and Distance to Shore σ (km) for all patch reefs by morphology.

.

Total	**2251**		**5.908**								

Results

The total number of patch reefs detected in the Lower Keys region was 2,251. Of these, the Aggregate morphology was the most numerous (1185) and was located the farthest from shore, averaging 7.4 km. The largest area of patch reefs was in Dome reefs, because of their large individual size and abundance (689). Dome reefs, along with Aggregate, Colony and Crescent patch reefs were abundant in the Mid-Shallow region (Fig. 4). Aggregate and Dome reefs comprise most of the patch-reef area on the outer shelf. Aggregate reefs tended to be much smaller (on average 1614 m^2) than the Dome reefs (2909 m^2), but because of their large numbers (1185 Aggregate patch reefs or 52.6% of the total number), the Aggregate patch reefs nevertheless represented the second largest group in terms of overall area (1.914 km^2 of the total 5.908 km^2, or 32.4% of the total area)(Table 1).

The distribution of all types of patch reef morphologies was heavily concentrated in the mid-shallow and offshore regions. This can be seen on the map in Figure 1, and is detailed in Figure 4.

The PAC shape index of each individual reef further reflects reef morphology. The corrected perimeter to area ratio (PAC) can serve as a useful indicator of the complexity of the reef shape, with a high PAC ratio indicative of a complex or elongated shape and a low PAC ratio indicating a compact, circular shape.

The mean PAC did not indicate substantial shape differences. The Colony reef shapes were the most complex, with PAC averaging 1.36. The Dome reefs were the least complex, and have PAC values averaging 1.26 (Table 1). As a whole, the mean PAC values were very similar among all of the morphologies.

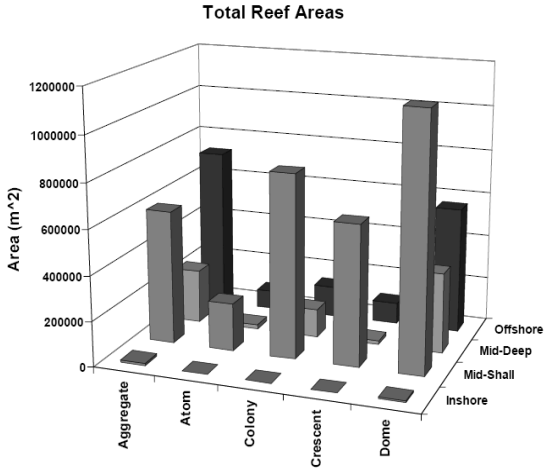

Figure 4: Total reef areas by class and distance from shore.

Discussion

The primary goal of this study was to identify and enumerate patch reef structures in the Lower Florida Keys Reef Tract using IKONOS satellite imagery. Using this method, 2,251 structures were identified. This is a substantial increase over previous estimates, more than six times Marzalek et al. (1977) and almost four times the FMRI (2000) estimates from aerial photography.

The qualitative characteristics that were initially observed in the patch reef dataset were not quantitatively demonstrated through the metrics we used. The patch reef data in Table 1 does not indicate that patch reefs have distinct morphologies and distributions in the Lower Keys, as was initially proposed. The summary data in Table 1 indicates that there exists high variability within morphological classes, and relatively small differences between them.

Future analyses will determine whether other metrics are more sensitive to – and can be used to quantitatively describe – the differences among patch reef morphologies

One inherent problem was that the reef parameters; area, perimeter, diameter, and the corrected perimeter to area ratio (PAC), were all affected by the 4 m pixel resolution of the original IKONOS imagery (i.e., polygons could not be delineated through the center of a pixel even if, in actuality, the edge of the reef may have). One possible way to better replicate the natural reef edge would be to use higher resolution (i.e. pan-sharpened or 1 m) imagery. This would alleviate this concern to a degree, however any delineation based on pixilated imagery would nevertheless result in a non-natural edge. A disadvantage of using higher resolution imagery is that it would greatly increase the amount of time spent analyzing the images.

A second possible limitation was that the patch reefs were subjectively classified by the observer and the data on a given reef were categorized under that class. Future multivariate statistical analyses will examine the reef-associated parameters independent of previously assigned classes.

Previous studies cited Florida Bay water and mobile calcareous sands as primary determinants of patch-reef growth, with patch-reef development focused on trough edges bordering Hawk Channel (Lidz et al. 2006). Key to our long-term analysis will be to determine how environmental and geological processes influence patch morphology and how this is manifested in the spatial distribution of patch reefs.

As live coral cover continues to decline, the importance of patch reefs in the Florida Keys will continue to increase. Under the working assumption that these patch reefs possess greater live coral cover than the offshore bank reefs, a comprehensive knowledge of their abundance, distribution, and controlling ecological parameters will be paramount.

Abstract. Macroalgae are important components of coral reef and seagrass ecosystems; however, the habitat structure macroalgae provide to the system has been little explored. We use architectural and morphological traits of macroalgae to describe and compare the reef and lagoon habitat complexity at Puerto Morelos reef in the Mexican Caribbean. Using a random-stratified method, macroalgae were sampled, then each organism was identified and morphometric features were recorded. A total of 101 species were found. The ordination analysis showed differences in species composition between the reef and lagoon. Small size, erect highly branched and dense clonal growth were more frequent in the reef compared to the lagoon where larger, erect, less branched and less dense algae with CaCO3 were found. Higher species richness and diversity of forms in the reef suggest a higher habitat complexity provided by macroalgae in the reef compared with the seagrass beds. The increase of fleshy macroalgae has been shown to decrease the habitat complexity provided by coral structure, we highlight that the increase of only some macroalgae species will result in a loss of complexity provided by other macroalgae species.

Key words: Plant architecture, clonal growth, Coral reef, Mexican Caribbean, Plasticity, Shift-phase

Introduction

Macroalgae are important components of coral reef and seagrass ecosystems, they help cement the reef framework and give refuge for numerous invertebrate and fish species (Gil et al. 2006); however macroalgae are increasing in abundance as a synergistic response to decrease of herbivores, increase of nutrients inputs, coral bleaching and coastal development, in both coral reefs and seagrass environments (Hughes et al 2005, Orth et al. 2006, Collado-Vides et al. 2007). Therefore a better understanding of the different roles macroalgae play on reef and seagrass systems is needed in order to protect and manage these resources.

Spatial complexity has been recognized as an important characteristic of habitats and is a major determinant of local abundance and diversity (Dahl 1973, Gratwicke and Speight 2005); moreover, architecture and density of macroalgae can influence the relationship between abundance and recruitment of other species in the community (Carr and Hixon 1995), therefore adding complexity to the reef system. For example, Hacker and Steneck (1990) demonstrated that architectural elements of algae (space between fronds) can be an important factor in determining demographic patterns of amphipods. Interpretation of macroalgal communities in marine habitats has been facilitated by the classification of species into functional-form groups proposed by Littler and Littler (1980), and Steneck and Dethier (1994). This approach characterizes species according to features such as body plan, behavior and/or life history strategy. Based on fundamentals from these authors we suggest that different habitats will be inhabited by different functional form groups, moreover, we suggest that these groups will in turn express different levels of habitat complexity.

The Puerto Morelos Reef system, in the Mexican Caribbean, is in a relatively good condition, and has a rich macroalgal flora both in corals as well as seagrass beds (Collado-Vides et al. 1998). We selected this site to explore a combination of community aspects such as: macroalgae community structure, functional form group distribution, and several architectural parameters as proxies to the evaluation of habitat complexity. In this study we describe and compare the reef and lagoon, adding a spatial structure perspective to the macroalgal community.

Material and Methods

This study was carried out at the Puerto Morelos reef, a section of the Mesoamerican reef system in 1998. The reef profile in Puerto Morelos has been divided into four main zones —lagoon, back-reef, crest, and fore-reef zone— based on its topographic

characteristics, coral species composition, and wave action (Jordan 1979). Substrate, water movement, and light are the most contrasting physical factors differentiating the lagoon and the reef area. The coral reef formation consists of corals of the genera *Porites*, *Acropora* and *Agaricia*, and some areas intermix with soft coral. The reef lagoon is characterized by seagrass meadows of the species *Thalassia testudinium* Banks ex Koenig mixed with bare sand patches and S*yringodium filiforme* Kuetzing in Hohenacker. Nutrient sources come mainly from the mangrove watershed through underground systems opening in springs in the reef lagoon.

Along this system, three contrasting areas were chosen as representatives of the range of habitat types: A) the fore reef and crest; B) deep lagoon and C) shallow lagoon. An imaginary line was laid out parallel to the shore trough these habitat types and these ones were considered as replicate transects. Each transect was then divided in five points: 1) La Bocana; 2) Astilleros; 3) ICMyL; 4) La Ceiba and 5) El Pueblo (Fig. 1). At each point, macroalgae were collected from four, non-overlapping, randomly-placed quadrants (0.25 m^2), for a total sample area of 5m^2 for each habitat. Based on the findings of Collado-Vides et al (1998), this sample area accounts for the maximum species found at each habitat type. All complete algal thalli present in the quadrants were collected by hand by SCUBA divers. Material was identified at species level and classified accordingly to morphological groups suggested by Steneck and Dethier (1994). In addition the following morphometric parameters were recorded in each plant: size (length in cm), type of growth (clonal or solitary); branching or frond density (non-medium-high); gregarious habit (solitary-regular-compact), attachment system (holdfast, rhizoids, stolon), anatomy (i.e. filament, blade, medullar) and presence-absence of $CaCO_3$.

Distributional patterns of species, in the range of habitat types, were analyzed by means of multivariate techniques that were applied to the presence-absence data matrix. A Bray-Curtis similarity matrix was obtained. No previous transformations were required. An ordination analysis by means of a non-metric multidimensional scaling program (MDS) was carried out. The Kruskal stress coefficient was applied in order to test the ordination obtained by the MDS using PRIMER VI package (Clarke 1993). A two way ANOSIM was used in order to test for significant differences between environments and seasons.

A contingency table was created with the distribution of species based on form-functional group classification. An X^2 was applied to the contingency table in order to find if the distribution of form-function groups were randomly distributed or differ as their interaction with environment. An ANOVA test was applied to the morphometric data comparing reef, lagoon and species present in both places. All statistic tests were conducted using the statistical package SPSS V. 13.

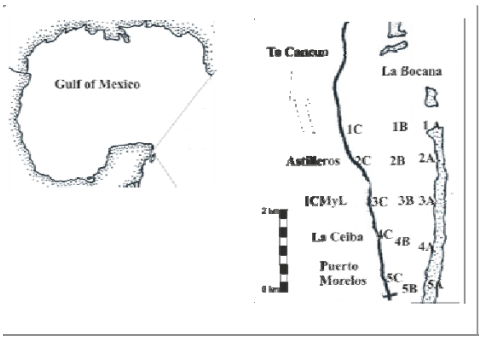

Figure 1: Study site and sampling stations. A= Reef sites, B= deep lagoon sites, C= shallow lagoon sties.

Results

A total of 101 species were found with a clear floristic difference between the reef and lagoon. A higher number of species, diversity and forms in the reef compared with the lagoon were found. Rhodophyta, which generally need hard substratum for attachment, were dominant in the reef, while Chlorophyta with sand-dwelling holdfasts were dominant in the lagoon. The most frequent large species found in the shallow and deep lagoon were the drifting brown species *Lobophora variegata* and *Dictyota bartayresiana* and sand-welling green species *Halimeda* spp., *Udotea* spp. and *Penicillus* spp; and no differences were found among seasons (Fig 2).

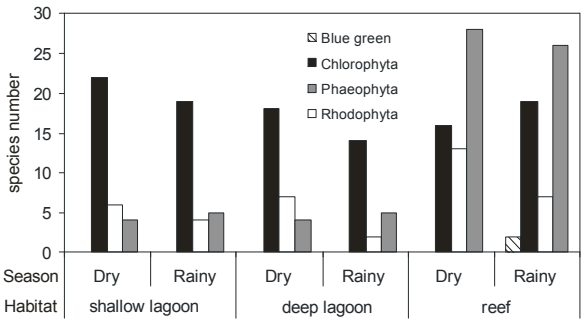

Figure 2. Total number of species at the reef, shallow and deep lagoon during both seasons sampled.

Species richness showed significant differences by habitat ($p<0.01$), with the highest richness found in the reef compared with the shallow lagoon and deep lagoon (23.1 ± 3.5, reef, *vs* 13.4 ± 3.9 and 12.9 ± 2.6, shallow and deep lagoon respectively). The MDS ordination analysis (Fig. 3) showed different species composition for the reef compared with the lagoon,

however shallow and deep lagoon were very similar among themselves (ANOSIM p>0.05).

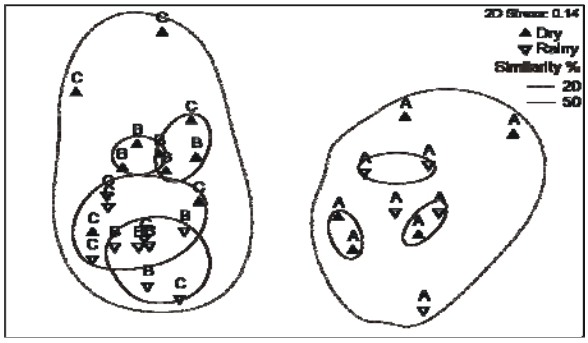

Figure 3: MDS configuration of species similarity matrix (stress= 0.14) for both seasons sampled and all sites. A= Reef, B= Deep lagoon, C= Shallow lagoon. Different line pattern shows different level of similarity between sites of different habitats.

The distribution of species classified on form-functional groups, demonstrated that different groups were present in the reef compared to the lagoon, x^2 = 63.37 (F=4, P= 0.0001) therefore form-functional groups were not randomly distributed. A higher diversity of forms was found in the reef with all 8 form-functional groups present, with the highest number of species belonging to the group of filamentous (turf forming) and corticated macrophytes. Five groups were present in the lagoon with the highest number of species belonging to the coenocytic group. Species present in both environments belonged to five form-functional groups without any group being dominant above the others (Table 1).

Table 1. Number of species belonging to each functional group and its frequency by habitat A= Reef, BC= Lagoon (shallow and deep), D= Reef and Lagoon. 1= Filamentous algae (uniseriate), 2 = Foliose algae (single layer), 2.5 = Corticated Foliose algae, 3 = Corticated macrophytes, 4 = Leathery macrophytes, 5 = Articulated calcareous, 6 = Coenocytic algae, 7 = Globular algae.

	Habitat			
FFG	**A**	**BC**	**D**	**Total**

2	2	0	0	2
2.5	5	1	7	13
3	17	1	4	22
4	6	0	0	6
5	9	3	5	17
6	6	18	5	29
7	6	1	0	7
Total	71	24	24	119

The morphological and architectural parameters had a distinct distribution of features among both environments. Small short organisms were found in the reef compared with those of the lagoon. Deep and shallow combined (ANOVA p<0.013), however no differences were found between reef and lagoon species that were present in both places (p<0.264), species present in both environments tended to have medium values, smaller than in the lagoon, but larger than the reef.

The orientation of the thallus: erect vs. prostrate reflects the way the thallus colonizes space, 85% of the reef and 87% of lagoon species had erect fronds with no clear stolon above ground, however all species that were found in both environments had prostrate arrangement of the thallus, mainly *Caulerpa* species. The attachment structures of the reef species were holdfasts or rhizoidal elongations which are strongly attached to hard substratum. Lagoon species had mainly rhizoidal systems either bulbous or just rhizoidal elongations that were embedded in the sand. Branching and gregarious habit which reflects how the thallus are packed in space, were significantly higher (p<0.04) in the reef compared to the lagoon showing a more compact and dense growth in the reef than in the lagoon. Species found in both environments tended to be more or less solitary with medium values of branching, among both extremes. More species with $CaCO_3$ were present in the lagoon than in the reef.

Discussion

The species composition found was similar to the species previous reported for the studied area and region (Collado-Vides et al 1998 for a review), at least in 1998 no strong shifts or macroalgal blooms were detected in the area, therefore this description can be used as a macroalgae base-line for present and future studies in Puerto Morelos, as no published historical records were found.

Species richness was higher in the reef than in the shallow and deep lagoon, this is consistent with the suggestion of McCoy and Bell (1991) that structural complexity of habitats is a major determinant of local abundance and diversity. The higher macroalgae species and architectural diversity found in the reef compared with the lagoon could be explained by the fact that corals offer a more complex environment due to the heterogeneity inherent to the form and shape of hard corals. This heterogeneity results in differences, at small scale in available space, water movement, and irradiation; therefore provide a greater spectrum of resources for macroalgae than seagrass beds (MacArthur and Levins 1967, Dahl 1973, McCoy & Bell 1991, Gratwicke and Speight 2005, Toohey et al. 2007).

Complexity in reefs is usually associated with different species of corals (Beukers and Jones 1997). Our study demonstrated that at least seven different

algal form-functional groups are present in the reef, adding layers of complexity to the already heterogeneous reef system. This is relevant as dominance of groups such as filamentous uniseriate algae, foliose algae (*Dictyota* type), and articulated calcareous green algae (*Halimeda* type), have been reported as main problems in reef systems going trough phase shifts due to environmental changes, (Gardner et al. 2003, Orth et al. 2006, Collado-Vides et al. 2007), therefore decreasing habitat complexity. Our findings agree with Lee (2006) in the fact that the increase of only one form-functional group (fleshy macroalgae) decrease the habitat complexity provided by coral, moreover we add that the increase of only a couple of species, within the fleshy macroalgae, will result in a loss of complexity provided by the diverse types of macroalgae present in a "healthy" reef system. The different scales at which each macroalgal group adds complexity will affect organisms functioning at such scale of complexity (Dahl, 1973). How the loss of complexity will impact the interaction with the following trophic level need to be addressed in long-term designed experiments (Toohey et al 2007), however we can assume that this loss can affect settlement (Lecchini et al 2007) and post-settlement (Eggleston 1995) of corals and survivorship of coral reef fishes (Beukers and Jones 1997).

The morphometric results showed that small size, erect highly branched and dense growth are more frequent in the reef compared to the lagoon where larger, erect, less branched and less dense algae are found. These morphological characters could be correlated to different environmental settings of water movement and substrate in the reef and lagoon at Puerto Morelos, since it is known that water movement differ through sections of Puerto Morelos coral reefs (Jordan 1979). In this regard, the small size, dense growths observed in reef species might be related to phenotypic plasticity to each site's hydrodynamic conditions, as turf-forming algae can tolerate and reduce water velocities (Hurd and Stevens 1997). This hypothesized hydrodynamic plasticity is especially evident for species found in both environments, for example Collado-Vides and Robledo (1999) described morphological and physiological plasticity in *Caulerpa cupressiodes* in Puerto Morelos reef system, where short and compact growth was found in the reef and larger less compact growth in the lagoon, a well recognized clonal strategy. Morphological characteristics, such as frond size, have been shown to affect dislodgment and survival in high-turbulence environments, such as intertidal zone (Carrington 1990).

Due to the karstic nature of the system, underground runoffs as well as isolated springs are the sources of nutrients from the watershed. We could expect a higher nutrient concentration on particular sites of the lagoon at localized springs, however our data showed that in general all sites in the lagoon had similar species composition, and the only strong difference was between reef *vs.* lagoon; therefore we are confident that the differences found, related with the goals of this study, are associated with the main significant difference between the reef and lagoon: substrate, water movement and light. An alternative explanation is that our sites were far away from springs and a direct effect of higher nutrient concentration was avoided. We do recognize that a more detailed study could detect differences in the macroalgal community as a function of nutrient sources as detected in other reef systems (Lapointe 1999). Particular algal morphologies have been related to nutrient uptake abilities (Littler and Littler 1980), and suggested to be used as potential indicators of nutrient sources in tropical systems (Fong et al 2001). Our results show a dominance of rhizophitic forms in the lagoon suggesting that macroalgae in the lagoon use nutrients from sediments, while *Laurencia* and other red attached species were found in the reef suggesting they have water column source (Fong et al 2001). Conducting a more detailed study including a survey of nutrient content of the different morphologies of macroalgae in order to detect sources of nutrients on the study site and its effects on the algal community is recommended.

This study show a high level of complexity in Puerto Morelos reef system, for the period studied, and in all categories used: number of species, number of functional-form groups and at the architectural level. In order to recover declining reefs and increase resilience in altered systems, we need to understand that macroalgae play different roles including being structural organisms.

Acknowledgement

This study was conducted with the support of DGAPA grant # IN 205495 and IN 215197 to LCV. The authors want to thank the ICMyL-UNAM at their marine station in Pto. Morelos, Quintana Roo, México for their support in the field work. We like to thank also to Luz María Arguelles for her help collecting samples. All the laboratory work was conducted at the Phycology Laboratory of the Science Faculty at UNAM. We are grateful to Anna Armitage and José Luis Carballo for providing helpful suggestions to improve the manuscript. This is SERC publication # 431.

Abstract. As part of the "Pilot project for the sustainable development of environmental sound management in South Sinai, Sharm el Sheikh, Ras Mohammed National Park" funded by the Italian Environmental Ministry we undertook underwater visual, photographic and video surveys along 15 belt transects. A bionomic and topographic map (scale 1:100) of the site selected for construction of an Underwater Observatory was made as part of the building plan of the structure.

Key words: Mapping, Belt transect, Coral reef, Red Sea, Egypt.

Introduction

Cartography of the sea bottom plays a key role in coastal management. Knowledge of the distribution of the main marine biocenoses is of fundamental importance in conservation and monitoring programs (Piazzi et al. 2000). The creation of habitat or geomorphology maps is a critical step towards the assessment and management of reef ecosystems (Andréfouët and Guzman 2005). Current applications of coral reef habitat maps include biogeochemical budgets (Andréfouët and Payri 2001) or resource assessment and exploitation planning (Long et al. 1993; Andréfouët et al. 2004). An interesting recent application is to use remotely sensed habitat maps as indirect guides for assessing biological diversity in the context of marine conservation, or to identify the scale of processes that controls the structure of a mosaic of habitats (Mumby 2001).

The present study was part of the "Pilot project for the sustainable development of environmental sound management in South Sinai, Sharm el Sheikh, Ras Mohammed National Park" funded by the Italian Environmental Ministry. Within this project the realization of a bionomic and topographic map of the site selected for construction of an Underwater Observatory was proposed in order to minimize direct impact on benthic organisms.

Material and Methods

The study area was located at Marsa Ghoslani in front of the Visitor Center of the Ras Mohammed National Park Park, Sharm el Sheikh (Egypt).

Due to the limited dimension of the area to be investigated and the high level of detail needed, it was decided to operate using a direct method of survey instead of indirect methods like those based on acoustic instruments or satellite images, better suited for broader scale investigation.

Visual, photographic and video surveys were made by SCUBA diving along 6m wide x 50m long belt transects (n=15) perpendicular to the coastline (Bianchi et al. 2003; Hill and Wilkinson 2004) (Fig. 1).

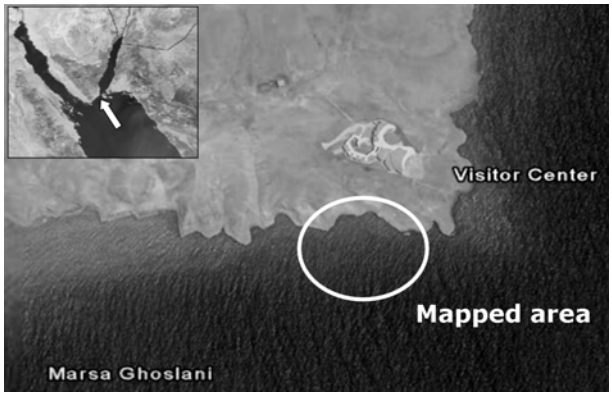

Figure 1: Study location along the coast of Sharm el Sheikh, Egypt.

The transects started from the reef crest and each starting point was positioned and georeferenced using a dGPS.

Visual recording of bottom features included type of substratum (rock, sand and rubble) and type of organisms (hard coral, soft coral). Bathymetric data were obtained measuring depth at each metre along the lines. Data were gridded using SURFER v. 8.0 (Golden Software, Inc.) to obtain the map.

Results

A bionomic and topographic map was obtained of a portion of marine bottom of about 5.000 m^2 (scale 1:100; reference point at 27°49.55'N, 34°16.14'E) (Fig. 2).

The map shows a fringing reef of only a few meters width. The reef flat is not continuous along the mapped coast, the interruption is visible on the map as the light grey area between the darker areas representing the fringing reef. When present, the reef descends from the crest to a depth of about 5 meters reaching a rocky platform covered by patches of sand, rubble and scattered living corals. In the mapped area this platform reaches depths of about 15-18 meters with a mean inclination of about 20%. The map clearly shows the presence and the distribution of living corals and some columns covered by a rich benthic community.

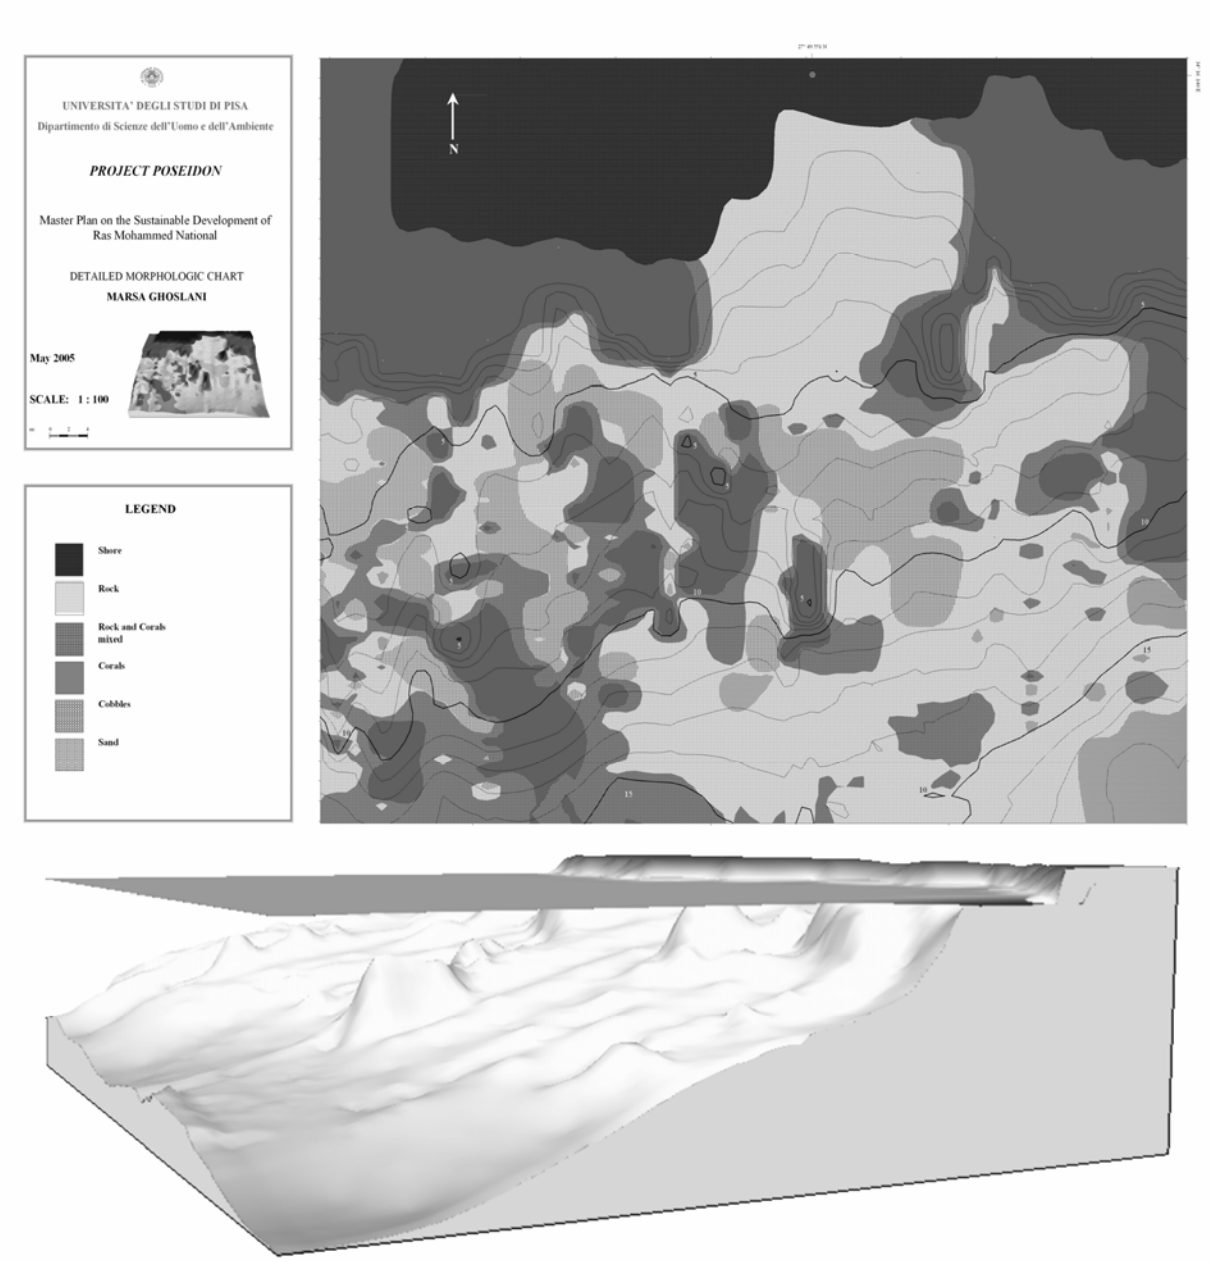

Figure 2: Bionomic and topographic map and three-dimensional representation of the bottom.

Discussion

Mapping bottom features is one of the essential steps to address environmentally sustainable solutions for underwater construction works. Of course, the knowledge of the extension and distribution of living corals must be considered as only part of the information necessary to manage this resource (Piazzi et al. 2000).

The map obtained from this study was used to elaborate the building plan of the Underwater Observatory. Suggestions were made regarding the type and shape of the structure and the route that it had to take in order to minimize direct impact on benthic organisms.

The Underwater Observatory consists of 3 structures: the underwater pipe-shaped tunnel, 58m long and with a diameter of 3m; the tower-lift, with a diameter of 6.5m that links the tunnel to the surface and that is connected to the coastline through a wharf 20m long and 5m wide.

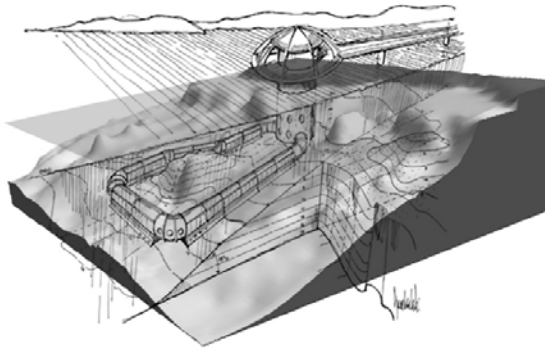

Figure 3: Sketch of the Underwater Observatory.

As can be seen in the sketch in Fig. 3, thanks to the map obtained, the ideal concept of the project plans to locate the underwater tunnel on the rocky bottom present in the area, thus avoiding the pinnacles covered by living corals. Moreover, it was possible to locate the wharf and the tower-lift where the fringing reef is naturally interrupted.

Acknowledgement

We would like to thank the scientists of EEAA (Egyptian Environmental Affair Agency), in particular to Dr. Essam Saadalla, for their collaboration during sampling activities and assistance in the field. A special thanks to our friend Anna Proietti-Zolla for her collaboration to this work and for her invaluable human support.

Abstract. In 1994, the Florida Keys Coral Reef Evaluation and Monitoring Project (CREMP) was initiated to provide status and trends data for the benthic reef resources of the Florida Keys National Marine Sanctuary (FKNMS). Forty sampling sites were selected within the FKNMS. Permanent station markers were installed in 1995 and annual sampling began in 1996. In 2007, an ongoing clionid sponge survey was expanded to include the barrel sponge, *Xestospongia muta,* at all CREMP monitoring stations.

The *Xestospongia muta* sampling method was developed based on existing CREMP project station layout with three 1-meter-wide belt transects providing the maximum spatial coverage within each station.

The distribution, abundance and volume of *X. muta* were analyzed sanctuary-wide, regionally and by habitat type for 103 sampling stations. Sanctuary-wide, 89% of abundance and 93% of volume were observed at offshore deep sites. At offshore shallow and patch sites 6% and 5% of total abundance and 5% and 2% of total volume were recorded respectively. *Xestospongia muta* was not observed at any hardbottom site sanctuary-wide. At the regional level, while sponges the Middle Keys had the greatest abundance and volume, the largest individual sponges were recorded in the Upper Keys.

Key Words: Florida, reef tract, sponge, *Xestospongia muta*

Introduction

Sponges are the most abundant sessile organisms in terms of biomass in many Caribbean reef communities (Diaz and Rützler 2001), and sponge species diversity may exceed that of corals (Wulff 2001). Sponges play many important roles in the reef ecosystem: filtering bacteria and nutrients from the water column, binding corals to the substrate, facilitating reef regeneration, and providing a food source for spongivores (Diaz and Rützler 2001; Wulff 2001). Sponges are also major competitors of corals in terms of reef space. Historically, data collection on sponges has been neglected in monitoring projects because sponge sampling poses a myriad of challenges to researchers. Field identifications can be difficult and sponge systematics is in flux on all taxonomic levels (Wulff 2001).

Since its inception in 1996, the Coral Reef Evaluation and Monitoring Project has documented stony-coral species richness through underwater inventories and percent benthic cover through video transects. These surveys are carried out at permanent stations throughout the Florida Keys National Marine Sanctuary. In 2001, the CREMP began monitoring the abundance and area of bio-eroding sponge species at all CREMP stations. The three clionid sponge species (*Cliona delitrix, C. lampa*, and *C. caribbaea*) recorded by the CREMP are known to be aggressive coral bio-eroders and over-growers (Callahan et al. 2007). In 2005, a fourth clionid, *Cliona varians* (formerly *Anthosigmella varians*), was added to the survey. In 2007, the barrel sponge, *Xestospongia muta* was added.

Xestospongia muta is commonly found on coral reefs and in subtropical hardbottom communities typically at depths greater than 10 m. This sponge is conspicuous and can be accurately identified in the field. It contributes greatly to overall sponge biomass due to its tremendously large size. Oscula diameters have been recorded as wide as 2.5 meters (Nagelkerken 2000). Populations of this species occupy greater than 9% of the available reef substrate in some regions (Zea 1993). Barrel sponges also have a tremendous filtering capacity and are an important source of inorganic nutrients. Sponges, including *X. muta*, host many prokaryotic (especially cyanobacteria) and eukaryotic symbionts and contribute significantly to reef productivity (Wilkinson 1983). *Xestospongia muta* is studied extensively for its secondary metabolite production. These sponges exhibit bleaching which, as in coral, may become fatal. Therefore

monitoring these sponges can be used as a metric for monitoring reef-community health. Mean specific growth rates as fast as 4.04 $year^{-1}$ and as slow as 0.02 $year^{-1}$ have been observed (McMurray et al). Specific growth rates of *X. muta* have been found to decrease with increasing sponge volume according to McMurray et al.

Including *X. muta* in the expanded CREMP sponge survey will provide data on the distribution, the number of individuals, and the size of these individuals in terms of volume. Changes in these values can be monitored over time at all of the CREMP stations throughout the Florida Keys National Marine Sanctuary. These data will help to elucidate the population dynamics, community structure, and health of these important and often understudied reef organisms.

Material and Methods

The same survey method was employed at each CREMP site. Thirty-eight sites (Fig. 1) comprised of 103 sampling stations were surveyed for *X. muta* in this 2007 study. The sites represent four habitat types: offshore shallow reefs, offshore deep reefs, patch reefs, and hardbottom communities. The CREMP sampling within the FKNMS encompasses three regions defined as Upper Keys (north Key Largo to Conch Reef), Middle Keys (Alligator Reef to Moser Channel), and Lower Keys (Looe Key to Smith Shoal) (Beaver et al 2006).

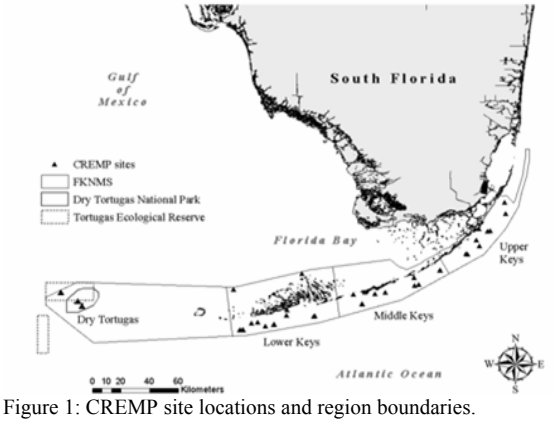

Figure 1: CREMP site locations and region boundaries.

Each sampling station within a site is permanently marked with two stainless steel reference stakes. Two steel poles, three plastic chains, and three measuring tapes mark a station's boundaries and define sampling transects (Fig. 2).

The sponge survey area is defined by three 1 meter wide belt transects within an existing CREMP station (Fig. 2). The survey area is delineated by a diver who swims directly above the transect tape and holds a meter stick perpendicular to the tape and parallel to the reef surface. The total station survey area is approximately $66m^2$. The diver records the location and volume of each *X. muta* encountered as well as notes on bleaching, disease, and scleractinian interactions. Every sponge observed can be relocated within the sampling station.

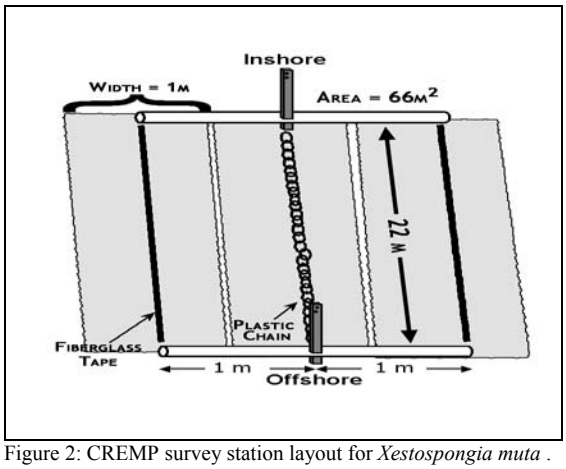

Figure 2: CREMP survey station layout for *Xestospongia muta* .

Because of the morphological plasticity of this sponge, volume was measured by approximation to various geometric solids such as cubes, prisms, cones, and spheres (Wulff 2001). The frustum, or truncated cone usually approximated the shape of *X. muta* most accurately. The radius of the apex (R1) and radius of the base (R2) were measured along with the height of the sponge (H1). These measurements were calculated as the volume of the frustum. The radius of the oscula (R3) and the depth of the oscula (H2) were also measured. The volume of this cone was subtracted from the volume of the frustum to provide a more accurate total sponge volume. The final equation for frustum volume calculations was:

$$1/3\Pi*H1[(R1^2 + R2^2) + (R1*R2)] - 1/3\Pi R3^2*H2$$

A custom designed underwater datasheet explicitly designed for this survey allowed for measurements to be recorded easily and accurately. Larger sponges were approximated to inverse frustums or cylinders. In 2008, underwater maps were created to relocate sponges previously sampled and identify new recruits at CREMP stations.

Results

Data on the distribution, abundance and volume were analyzed sanctuary-wide, regionally and by habitat type for 103 sampling stations. One CREMP station equals one sample.

Sanctuary-wide Distribution by Habitat Type

Sanctuary-wide, 89% of abundance was observed at offshore deep sites, while sponges at offshore shallow and patch sites made up 6% and 5% of abundance respectively (Fig. 3). Offshore deep sites contained 93% of total sponge volume, while sponges at offshore shallow and patch reefs contributed only 5% and 2% respectively (Fig. 4). No *X. muta* were observed at any of the three hardbottom sites sanctuary-wide.

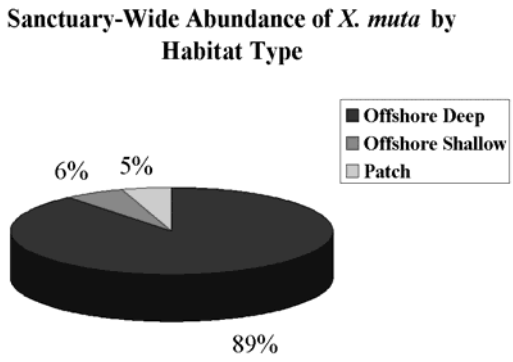

Figure 3: Sanctuary-wide abundance of *X. muta* by habitat type. No individuals were found at any CREMP hard-bottom stations.

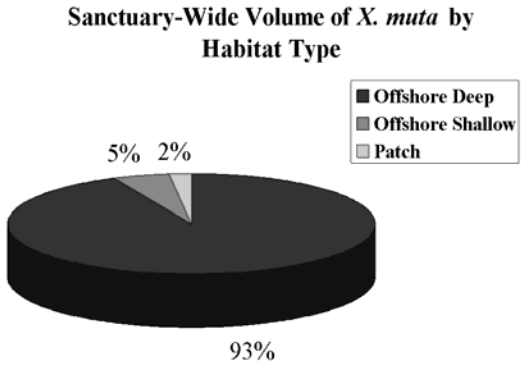

Figure 4: Sanctuary-wide volume of *X. muta* by habitat type.

Abundance: Regionally and by Habitat Type

At the regional level, sponges at sites in the Middle Keys (29 stations) contributed the greatest mean (+/- 1 SE) abundance (0.051 +/- 0.015 individuals/m^2). Abundance ranged from 0.015 individuals/m^2 at several stations to 0.333 individuals/m^2 at Tennessee Deep station 4. This station had the greatest *X. muta* abundance of all those surveyed by the CREMP. Sponge abundance recorded in the Upper Keys (28 stations) was 0.023 +/- 0.011 individuals/m^2, while the abundance in the Lower Keys (46 stations) was 0.046 +/- 0.012 individuals/m^2 (Fig. 5)

When abundance is examined by habitat type, the greatest abundance (0.172 +/- 0.043 individuals/m^2) was at offshore deep sites in the Middle Keys. The Upper Keys deep sites had the least sponge abundance (0.101 +/- 0.036 individuals/m^2), while the Lower Keys deep sites had a sponge abundance of 0.143 +/- 0.021 individuals/m^2 (Fig. 6).

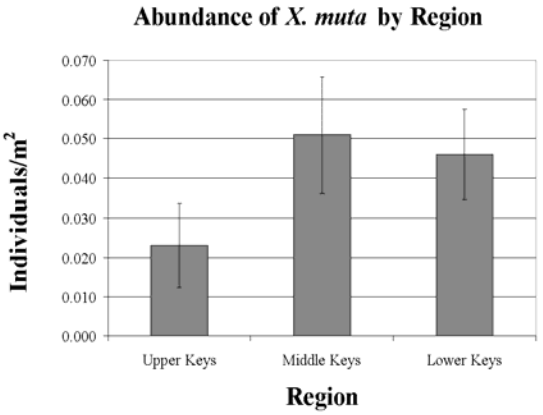

Figure 5: Abundance of *X. muta* by region

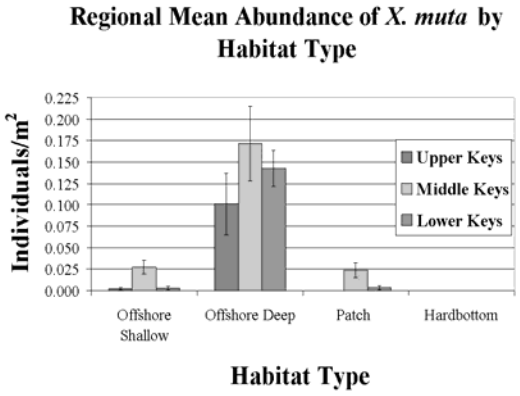

Figure 6: Regional mean abundance of *X. muta* by habitat type. No individuals were recorded at Upper Keys' patch reefs

Volume: Regionally and by Habitat Type

In all regions offshore deep sites had the highest mean (+/- 1 SE) sponge volume. The Middle Keys' deep stations had the greatest sponge volume (2100 +/- 1057 cm^3/m^2). The Upper Keys' deep reefs had the next highest sponge volume (1609 +/- 624 cm^3/m^2). The Lower Keys' deep reefs had the least *X. muta* volume with 960 +/- 172 cm^3/m^2 (Fig.7). The lowest sponge volume by station was 8.31 cm^3/m^2 at Sand Key Deep station 3, and the greatest sponge volume by station was found at Tennessee Deep Station 4 with 7207 cm^3/m^2. The largest individual sponge was recorded at Molasses Deep station 1 (133,070 cm^3), while the smallest

individual sponge was recorded at Eastern Sambo Deep station 3 (1.05 cm^3). The largest individuals by sponge volume were at Upper Keys' deep stations (Fig. 8).

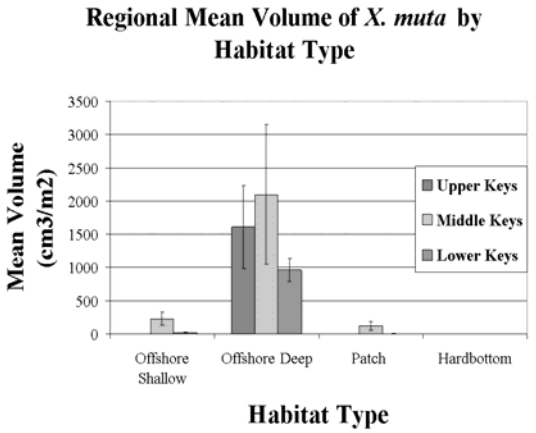

Figure 7: Regional mean volume of *X. muta* by habitat type

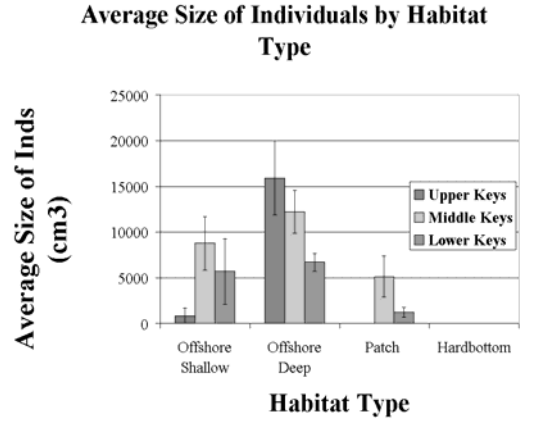

Figure 8: Average size of individual *X. muta* by habitat type

Surface area

When sponge data for all CREMP stations are averaged, the surface coverage of *X. muta* is under 1%, but when only data for the offshore deep sites are considered, surface area increases. The average *X. muta* coverage at offshore deep sites is 1.26%. The range varies from 1.71 cm^2/m^2 or 0.26% to 295 cm2/m2 or ~4.5% at Tennessee Deep station 4.

DISCUSSION

Xestospongia muta is Most Abundant at Deep Sites

In the present effort we have surveyed offshore shallow reefs, offshore deep reefs, patch reefs, and hardbottom habitats for the presence of the barrel sponge, *Xestospongia muta*. We obtained measurements on the number of individuals and volume to describe the population. This initial survey will serve as a baseline year for additional years of monitoring and further research projects.

It was expected that sponge abundance and volume dominated the FKNMS at the offshore-deep reef sites. Sponges at Middle Keys' deep sites averaged 0.172 individuals/m^2. *Xestospongia muta* is typically found at depths greater than 10 meters. The CREMP offshore-deep sites are the only sites sampled with these depths. However, *X. muta* was not present at every offshore deep site sampled. In the Upper Keys none were observed at the two stations comprising the Carysfort deep site. This was the only deep site sampled that had no *X. muta*. The depth range at this site is between 12.5 m and 16.2 m which is a typical depth range of *X. muta* habitat. Additional research on water-quality conditions and ocean currents may provide insight as to the absence of the sponge at this site. At Western Sambo deep in the Lower Keys, *X. muta* was present at two stations with a depth of 12 m, but absent at the third station, which had a shallower depth of 6.7 m. Nutrients and particles in the water column at this shallow station may be insufficient to support these large sponges. There are observational data for the presence of *X. muta* at shallow reefs (less than 5 meters in depth) in the Caribbean (Smithsonian Tropical Research Institute 2003). Data recorded in this study from offshore shallow reef sites (Fig. 6) support those observations. Shallow reef sponges were less barrel-shaped than those at deep sites, but were vase-shaped and usually projecting out from under an overhang. Few sponges were recorded at patch reef sites (0.007 individuals/m^2), but at several non-CREMP patch sites (less than 10 meters in depth) several barrel sponges were observed (M. Bertin pers. obs.).

Sponge volumes in this study ranged from 1.05 to 133,070 cm^3. This range is similar to those (24.05 to 80,281.67 cm^3) observed by McMurray et al. *Xestospongia muta* covered an average of 1% of available reef substrate at CREMP stations, but this sponge covered 4.5% of available substrate at Tennessee Deep station 4. This cover value is about half of that reported by Zea in 1993 (>9%).

No observations of bleaching and disease were recorded in this 2007 study. However, spots determined to be grazing scars were observed on several individuals. Parrotfish are known grazers of *X. muta* and the grazing is increased on those sponges that have bleached (Dunlap and Pawlik 1998). This may be from reduced chemical defenses in the bleached sponge (Dunlap and Pawlik 1998). Additional years of study may provide greater knowledge of in situ bleaching, disease, and grazing identification. Several sponges were observed with large holes which were surmised to be damage from anchors.

This study showed that the greatest abundance and volume of *X. muta* is at the CREMP offshore deep reef sites (Figs. 3 and 4, 14 expected individuals/100 m^2 at deep CREMP sites versus 0.9 and 0.7 individuals/100m^2 at offshore shallow and patch sites).

Abstract. We report the results of a multi-site comparative analysis of coral reef condition along a gradient of coastal development in the Yucatan Peninsula (Mexico). Benthic surveys and fish counts performed in 2000 were used to assess ecosystem structure and functional reef components in three regions of the State of Quintana Roo: 1) the Riviera Maya in the north, with heavy tourist development; 2) the Sian Ka'an Biosphere Reserve, a protected area with very low human density; 3) the Costa Maya in the south, with relatively little tourist development. Results showed significant differences in the ecological state of coral reefs along the coast. Northern reefs exhibited an algal-dominated state with a very low coral cover, whereas southern reefs exhibited a more balanced coverage of macroalgae and corals with extended areas of free substrate. No clear trends were apparent in the spatial patterns of the biomass of herbivorous fishes, but fish functional diversity decreased from south to north. Results suggest that massive coastal tourism development combined to a low resilience may have caused major shifts in the structure and function of coral reefs in the northern region of the Yucatan Peninsula.

Key words: Macroalgae, Herbivorous fish, Functional diversity, Tourism, Disturbance.

Introduction

Caribbean coral reefs have been suffering a regional-scale decline as a result of multiple disturbances (Gardner et al. 2003, Wilkinson 2004). Increasing coastal development calls for a better understanding of the key processes driving coral reef degradation since the causes and mechanisms leading to this decline are still debated (Aronson and Precht 2006, Mora 2008). In addition, reef management requires functional approaches to understand how disturbances affect the structure and function of coral reefs (Hughes et al. 2003, Bellwood et al. 2004).

The Mesoamerican barrier reef system is home to some of the richest biodiversity in the wider Caribbean, but it is threatened by intensive coastal development induced by fast-growing tourism industries (Kramer and Kramer 2002, Wilkinson 2002, 2004). Along the Caribbean coast of the Yucatan Peninsula (Mexico), the State of Quintana Roo has endured a massive tourism development, starting on Cancun in the 1970s and extending towards the south during the last three decades. Given the strong anthropogenic pressure, the ecological state of Quintana Roo coral reefs needs to be evaluated to search for possible impacts of coastal development.

We report the results of a multi-site comparative analysis of coral reef condition along the Quintana Roo coast. A functional approach, based on the assessment of key functional components of benthic and fish communities, was developed to evaluate the potential impacts of anthropogenic disturbances.

Material and Methods

Study area

Mexican Caribbean coral reefs extend for over 400 km along the coast of the State of Quintana Roo on the eastern side of the Yucatan Peninsula (Fig. 1).

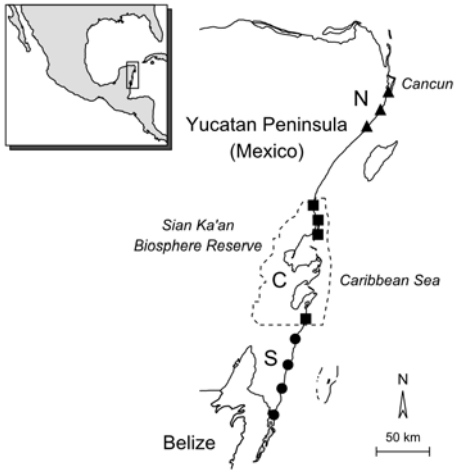

Figure 1: The 11 study sites in the northern (N, triangles), central (C, squares) and southern (S, circles) Quintana Roo coast.

Quintana Roo reefs are referred as extended fringing reefs and vary slightly from a gentle slope with low relief in the north to better developed reefs with spur and groove formations in the south (Jordán-Dahlgren and Rodríguez-Martínez 2003, Núñez-Lara et al. 2005). According to human use and coastal development, the Quintana Roo coast can be broadly divided into 3 regions: the Riviera Maya in the north (N) with heavy coastal development, especially in Cancun; (2) the Sian Ka'an Biosphere Reserve in the central region (C) with very low human density and a protected status; the Costa Maya in the south (S) with low human density and small but rising tourism development.

Data collection

Fish counts and benthic surveys were performed (Núñez-Lara 2003) in 2000 on the 6-m deep fore-reef zone of 11 reef sites distributed in the three regions N, C and S (Fig. 1). Fish censuses were conducted on 18 replicate 50 x 2-m belt transects and species biomass was subsequently estimated from individual size using length-weight allometric relationships compiled in FishBase (Froese and Pauly 2008). Benthic coverage was assessed from digital video imagery (Osborne and Oxley 1997), video transects being later analyzed using a point sampling method. A plastic sheet marked with 13 points was laid over a monitor screen, and sessile organisms and substrate types lying beneath each point were counted on 40 regularly spaced frames. For each video transect, percentage cover of benthic components was then estimated from 520 point counts.

Finally, we gathered socio-economic indices for the coastal municipalities (the second-level administrative division in Mexico) of the Quintana Roo state for the period 2000-2002. Urban areas and road density (SEPLADER 2006), human density (INEGI 2000) and number of hotels (SEDETUR 2008) were used to quantify the anthropogenic pressure along the Yucatan coast.

Data analysis

Percentage cover of fleshy macroalgae (canopy height >1 cm), live corals (scleractinians and gorgonians) and bare substratum (i.e., free hard substrate) was compared in the regions N, C and S of the Quintana Roo coast. Total fish biomass and fish herbivore biomass (*Scaridae* and *Acanthuridae*) were also compared, as well as the number of fish species per transect. Comparisons between the three regions were performed using pairwise t-tests with the Bonferroni correction. Finally, functional diversity (species richness by functional group) was investigated by pooling fish species into 28 functional groups defined by feeding habits, size and mobility. For each reef site, we estimated the number of fish species (SR) by functional group, and mean SR per group were calculated 1) over all reef sites (global mean SR) and 2) over the reef sites of each region (regional mean SR). Deviations of regional means to the global mean were analyzed for each functional group.

Results

Indices of coastal development

Socio-economic data indicated a clear gradient of coastal development along the Quintana Roo coast (Fig. 2). Urban areas and human density decreased strongly from north to south. In addition, tourism infrastructure was far more developed in the north: the number of hotel rooms reached 25,000 in Cancun and decreased to about 15,000 along the whole Riviera Maya, then 100 and 200 in the Sian Ka'an Biosphere Reserve and in the Costa Maya respectively.

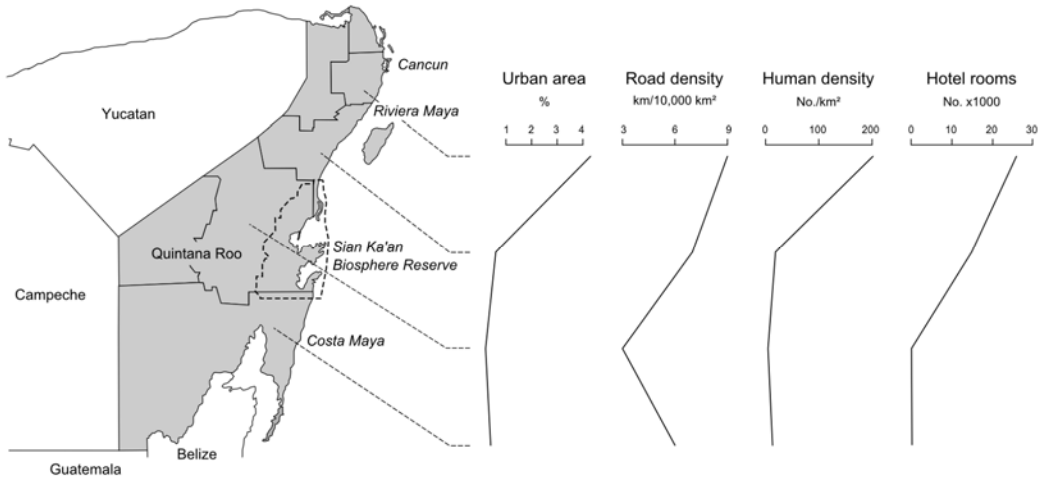

Figure 2: Indices of coastal development for the 4 coastal municipalities of the Quintana Roo state.

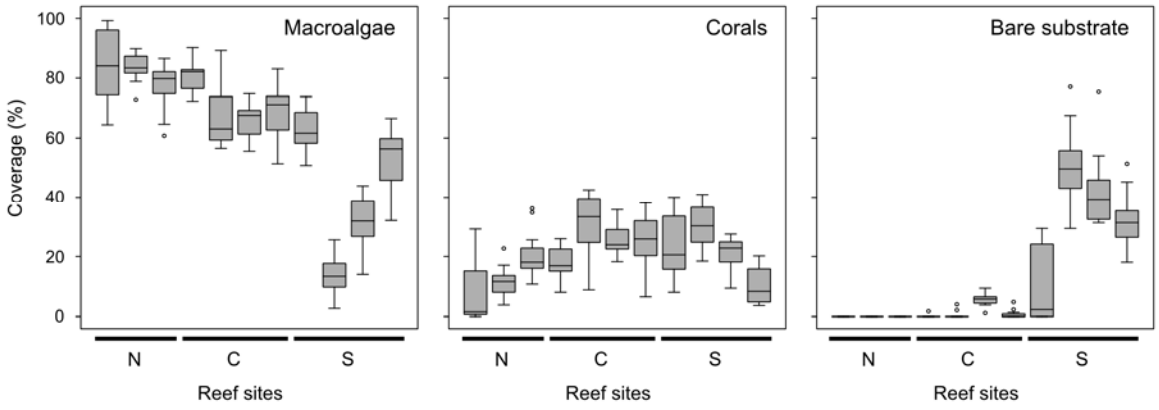

Figure 3: Benthic coverage of macroalgae, corals and bare substratum at the 11 surveyed reef sites of the Quintana Roo coast.

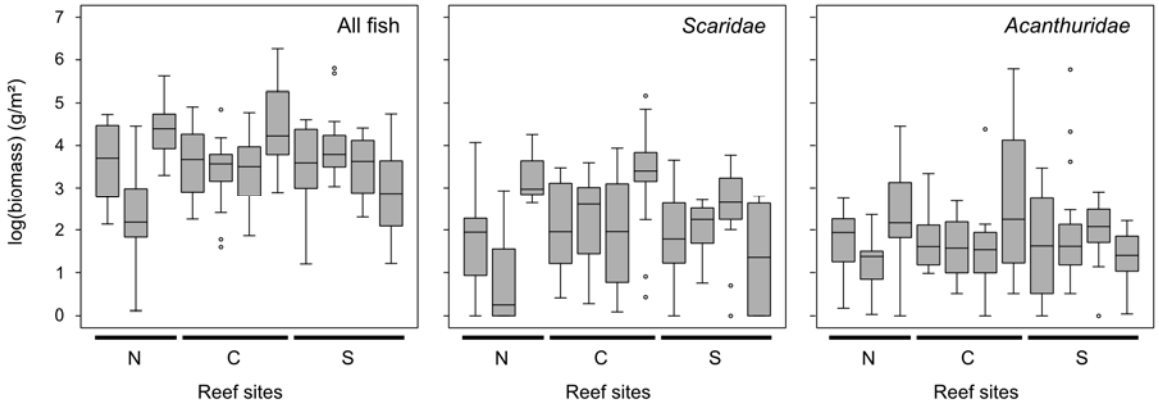

Figure 4: Total fish biomass and biomass of *Scaridae* and *Acanthuridae* at the 11 surveyed reef sites of the Quintana Roo coast.

Benthic cover

The percentage cover of macroalgae was higher in the north (Fig. 3, mean ± s.e. 82 ± 1%) and decreased significantly ($p<0.001$) in the central region (71 ± 1%), then in the south ($p<0.001$, 38 ± 3%). Maximum values were observed in the far north (10-km south to Cancun) where macroalgal cover reached 95% in several places. Coral cover was significantly lower ($p<0.001$) in the north (13 ± 1%) than the other regions (C: 25 ± 1%, S: 22 ± 1%). The coverage of bare substrate was null in the northern region and increased to the south where it reached one third (35 ± 3%) of the reef bottom.

Fish biomass

Total fish biomass (mean ± s.e. 58 ± 6 g/m²) was highly variable between and within reefs (Fig. 4) but did not vary significantly between the three regions. In average, herbivores accounted for 49% (± 3) of the total biomass of fish assemblages. Biomass of *Scaridae* was significantly higher in the central region compared to the north ($p<0.05$) and the south ($p<0.01$). The biomass of *Acanthuridae* did not vary significantly. As a result, herbivore biomass and macroalgal cover did not show a significant relationship along the Quintana Roo coast.

Fish diversity

Fish species richness (Fig. 5) was significantly lower ($p<0.01$) in the north (11.4 species/transect) than the central region (14.3 sp.) and the south (15.5 sp.).

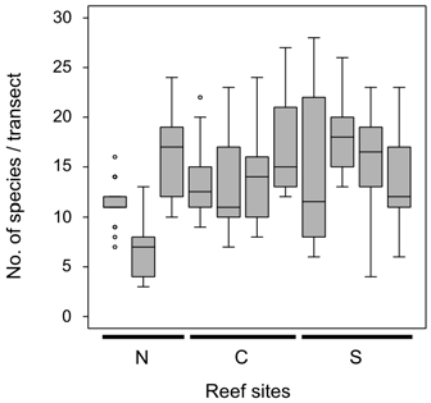

Figure 5: Fish species richness along the Quintana Roo coast.

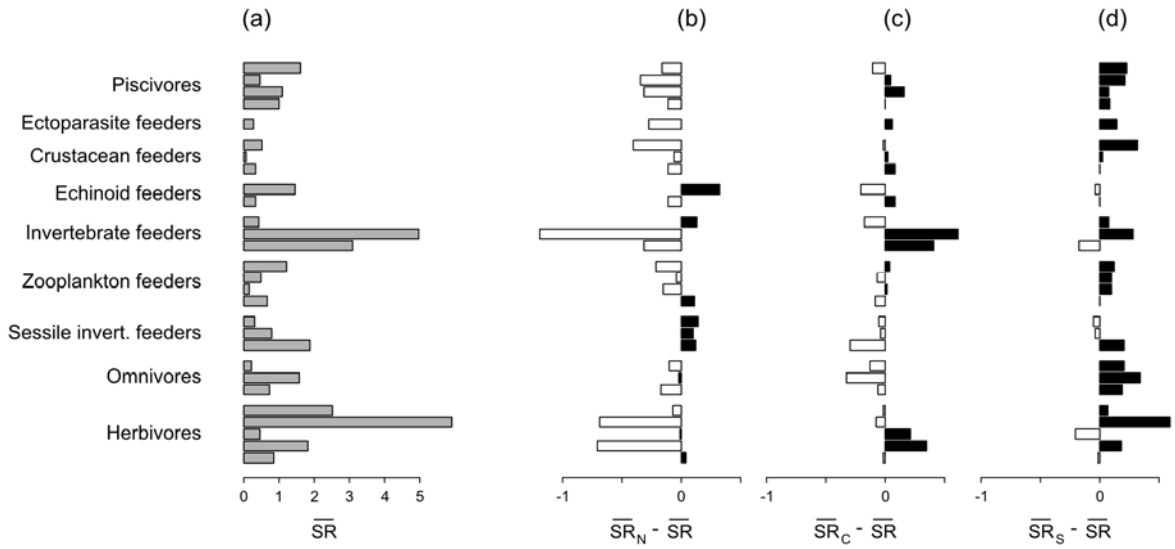

Figure 6: Fish functional diversity along the Quintana Roo coast described by (a) the global mean species richness (SR) of the 28 functional groups and deviations from the global mean SR to (b) northern, (c) central and (d) southern mean SR.

Fish functional diversity also increased from north to south (Fig. 6). Species richness of some herbivore, invertebrate feeder and high-level carnivore groups increased. Inversely, some functional groups, such as echinoid feeders and sessile-invertebrate feeders, were more speciose in the north.

Discussion

In 2000, the benthic structure of coral reefs exhibited highly contrasted patterns along the Quintana Roo coast. Northern reefs were largely dominated by macroalgae (82% mean coverage) and live coral cover was very poor (13%), whereas southern reefs exhibited a more balanced coverage of macroalgae and corals (38% and 22% respectively) with extended areas of bare substrate available for colonization. Those patterns indicate considerable changes in the equilibrium between macroalgae and corals following a north-to-south latitudinal gradient. From southern to central reefs, macroalgae progressively overwhelmed the available free space, and then overgrew corals in the northern region until they dominated and saturated the reef bottoms. Those patterns indicate a latitudinal gradient of coral-to-algae phase shift along the Quintana Roo coast. This gradient of ecological states suggests a major shift along the coast in the processes driving the equilibrium between macroalgae and corals.

In the recent decades, many Caribbean reefs have suffered major declines in coral cover leading to a phase shift from hard coral to fleshy algae dominance (Gardner et al. 2003, Pandolfi et al. 2005). Coral-to-algal phase shifts have been attributed to the reduction of herbivory as a result of diseases (mass mortality of the echinoid *Diadema antillarum*) and overfishing (Hughes 1994, Jackson et al. 2001, Mumby et al. 2007). From north to south, no clear trends were apparent in the biomass of herbivorous fishes on Yucatan reefs. Spatial information of the fishing pressure is scarce, but *Scaridae* and *Acanthuridae* are seldom targeted by Mexican fishermen. In addition, *Diadema* urchins did not recover in 2000 from the 1983-84 mass mortality event as only few isolated individuals were detected on videotransects. As a result, fishing pressure and herbivory are unlikely to have caused the benthic shifts observed along the Quintana Roo coast.

Other explanations of coral-to-algal phase shifts involve coastal development and associated nutrient enrichment (Lapointe 1997). In 2000, the Quintana Roo coast exhibited clear patterns in coastal development that fitted very well with the gradient depicted on the benthic structure. From the poorly developed coast in the south to the heavy touristic spot of Cancun in the north, urbanization, coastal population and tourism infrastructure sharply increased parallel to the latitudinal gradient of macroalgal proliferation. This suggests that tourism-driven coastal development may be the primary cause of coral-to-algal phase shifts detected along the Quintana Roo coast.

Other processes such as hurricanes and coral mortality have the potential to inverse the equilibrium between corals and algae (Ostrander et al. 2000, Aronson and Precht 2006). Coastal development may have affected reef resilience on Quintana Roo reefs and increased their susceptibility to natural disturbances. Ecosystem responses to disturbances vary according to ecosystem functions performed by organisms, and functional diversity and redundancy

(i.e., the number of taxonomically distinct species that exhibit similar ecosystem functions) can be expected to strongly influence coral reef susceptibility to coral/algal phase shifts (Bellwood et al. 2004, 2006). Our results showed a lower functional redundancy in northern fish community of some key functional groups, such as herbivores and piscivores. This may indicate that northern reefs were more susceptible to anthropogenic disturbances, or that benthic shifts have impacted the species composition of fish assemblages (see also Arias-González et al., in press). Our data do not allow to conclude if the spatial patterns of functional diversity are the result or the partial cause of the ecological changes depicted on the reef benthic structure. They suggest however that the potential of reef resilience is probably lower in northern reef in face to disturbances.

In 2000, macroalgae dominated northern reefs of the Yucatan Peninsula, and coral/algal phase shifts extended towards the south. During the last decade, coastal development has grown faster, stretching from Cancun to the northern edge of the Sian Ka'an Biosphere Reserve. The expanding costal development and the low redundancy of some functional groups are unlikely to have helped northern reefs to recover. In addition, tourism economy has reached southern reefs with the construction of a cruise ship pier for the development of tourism industry in the Costa Maya. Management actions are needed to protect the last healthy reefs of Quintana Roo coast which face a massive tourism development. As reported in the present study, coral cover was higher in some reef sites of the Sian Ka'an Biosphere Reserve, despite an algal-dominated state. Such patterns may encourage the development of protected areas to help coral reefs to maintain a substantial coral cover. Finally, this study provides a reference point of coral reef condition along the Quintana Roo coast, and future management of coral reef resilience may be improved by continued assessment of ecosystem metrics and functional attributes of species.

Abstract. The southern Seychelles Islands suffered extensive bleaching-related losses of live coral habitat in 1998. The Aldabra Marine Programme investigated coral-bleaching-related responses in reef fish communities at the UNESCO-protected Aldabra Atoll and neighboring unprotected Assomption, Astove and St Pierre. These were all coral-rich systems before up to 50% loss of live corals. Hard coral recovery has been minimal except at St. Pierre. Habitat phase shifts have occurred only at Aldabra (soft coral, *Rhytisma*) and at Assomption (macroalgae, *Halimeda*). Fish abundances by species at Aldabra were different between sites and years, but there was no directional change within sites. Multivariate comparisons of fish assemblages at 10m and 20m depths showed no directional changes over time at Aldabra (1999-2006), Assomption (2002-2006), Astove (2002-2005), and St Pierre (2002-2005). At Aldabra, pre-bleaching reef fish community structure persists, and abundance changes appear to represent the "natural" system. Similar patterns at neighboring unprotected islands suggest any anthropogenic impacts are below the thresholds affecting local reef-resident species. Losses of live coral in these coral-rich communities apparently were not catastrophic disturbances that pushed these ecosystems beyond their "tipping point" which would reduce resilience and lead to changes in the basic structure of the reef fish assemblages.

Key Words: Words: bleaching, fish assemblages, catastrophic disturbance, tipping point

Introduction

The 1998 El Niño-related warm water event resulted in mass losses of corals due to bleaching that altered reef habitats on a historically unprecedented global scale (Hoegh-Guldberg 1999, Wilkinson 2004). The western Indian Ocean suffered some of the most severe bleaching-related coral mortality during this 1998 event, with up to 90% of the live corals in the region affected by bleaching (Wilkinson et al. 1999). In the southern Seychelles Islands there were extensive bleaching-related losses of live coral habitat on the outer reefs, with coral mortality ranging from 60-75% and losses of live coral cover as high as 60% (Teleki et al. 1999, Spencer et al. 2000, Spalding and Jarvis 2002, McClanahan et al. 2007). Aldabra Atoll and the neighboring southern Seychelles islands of Assomption, Astove and St Pierre were coral-rich systems prior to losses of up to 50% of live coral in the 1998 bleaching-event (Spalding and Jarvis 2002, Stobart et al. 2005, Downing et al. 2006). A 1998 survey of the outer reef scleratinians at Aldabra Atoll during the late stages of the bleaching event found 36-100% recently bleached or dead depending on depth (Spencer et al. 2000).

Losses of live coral of this magnitude often result in decreased structural heterogeneity of the reef habitat through erosion of the dead coral framework. The associations between reef fishes and coral habitat complexity (review in Wilson et al. 2006) support the conclusion that reef fishes should be affected by mass losses of corals. However, studies of the responses of fishes on different reefs from 1-6 years after the 1998 mass bleaching have yielded mixed and differing results (Spalding and Jarvis 2002, Bellwood et al. 2006, Garpe et al. 2006, McClanahan 2006).

In a controlled experiment Holbrook et al. (2006) found that the amount of live coral habitat can influence fish assemblages, including fishes that have generalized habitat requirements (i.e., non-coral-obligate species). Further, this experiment suggested that on coral-rich reef habitats there must be an almost catastrophic loss of live coral cover to substantially change the basic structure of the fish assemblage.

Here we use results of long term monitoring of the coral reef communities at Aldabra Atoll and the neighboring islands of Assomption, Astove and St. Pierre to assess responses of the associated fishes to the extensive and massive 1998 bleaching-event losses of live coral. These four locations were coral-rich systems prior to 1998. We investigate if changes in the coral habitat in 1998 represented catastrophic disturbances for local fish assemblages. The surveys at one protected and three unprotected locations provide information on responses of local fish populations to any synergy between bleaching and direct anthropogenic or fishing impacts.

Methods

Quantified digital videography surveys of the benthic habitats, and quantified visual surveys of species and size-groups of fishes, were conducted by the Aldabra Marine Programme (AMP) on the outer reefs at Aldabra Atoll, and Assomption, Astove and St. Pierre Islands (Fig. 1). Surveys were along permanently marked transects on the 10 m and 20 m depth contours (for protocols see Teleki et al. 1999). Surveys at Aldabra Atoll conducted at Sites 1-4, 6 and 8 (Stobart et al. 2001) along the northern shore were used for this study. Site 5 had atypical coral rubble habitat, and Site 7 transect depths were 5m and 15m. Surveys at Aldabra were during November 1999, February 2001 and 2002, May 2003, March 2004 (incomplete surveys), April 2005 and December 2006. Surveys were conducted at one site each at Assomption, Astove and St. Pierre during February 2002, May 2003, March 2004 (incomplete surveys), and April 2005, and at Assomption during December 2006 (Stobart et al. 2002).

The habitat video imagery was analyzed using the AIMS 5-dot method (Osborne and Oxley 1997) and used to compare the annual percentage change in corals, algae and other habitat categories. PRIMER multivariate comparisons (MDS) were made of the abundance of fishes between years, tested for linear sequence (RELATE), and at Aldabra Atoll tested for differences between sites (ANOSIM; Clarke and Warwick 2001).

Results

Benthic habitats

At Aldabra Atoll the increases in live coral cover since the post-bleaching survey in 1999 were driven by extensive growth of the soft coral *Rhytisma* at both 10m and 20m (Fig. 2). There was little change in the growth of other soft corals at either depth. Recovery of hard corals was minimal at 10m and 20m. Macroalgal cover declined at both 10m and 20m to the lowest levels recorded in the eight years following the bleaching event. Erect dead coral habitat continued to decrease at both 10m and 20m (see AMP reports available at http://aldabra.org).

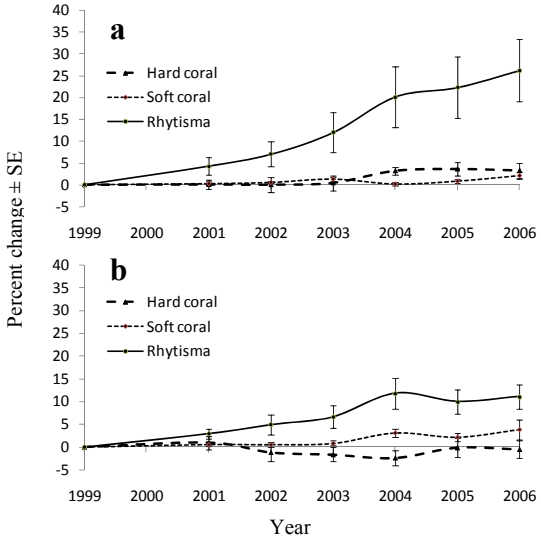

Figure 2. Change in hard coral, soft coral and *Rhytisma* at Aldabra atoll (see legend) at a) 10m and b) 20m depth between 1999 and 2006.

At Assomption, Astove and St. Pierre, the growth of *Rhytisma* and other soft corals was minimal, although relatively more pronounced at Assomption. The soft corals were not important factors in any increases in live coral cover at either 10m or 20m. Increases in hard coral cover were minimal at Assomption and Astove, but relatively large and steady at St. Pierre at 10m and 20m, driven by recruitment of *Pocillopora eydouxi* (Fig. 3). Macroalgal cover was a minor part of the reef habitat at Astove and St. Pierre, but at Assomption there was a rapid increase in macroalgal cover (primarily *Halimeda*) at 10m, and a steady, but less dramatic, increase at 20m following a major decrease in macroalgae at this depth in 2003. Erect dead coral

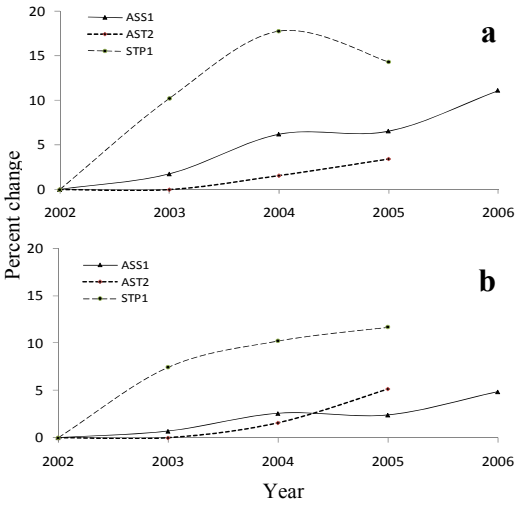

Figure 3. Change in hard coral at Assomption, Astove and St. Pierre (see legend) at a) 10m and b) 20m depth between 2002 and 2006.

formed minimal habitat at Assomption, Astove and St. Pierre at both 10m and 20m, and is generally decreasing.

Fish surveys

The number of species in the annual fish surveys were as follows: Aldabra Atoll – avg. 178, ra. 138-191; Assomption – avg. 90, ra. 88-92; Astove – avg. 88, ra. 83-94; St. Pierre avg. 108, ra. 107-110. At Aldabra the annual means of fish abundances by species, taking into account site differences, showed there were significant differences between sites and years at both 10m and 20m (ANOSIM: Year – 10m P = 0.02, Rho = 0.425; 20m P = 0.03, Rho = 0.316; Sites – 10m P = 0.01, Rho = 0468). However, there were no directional changes following a linear sequence within sites (multiple Figures not shown), with the exception of Site 4 (20m) where there was high annual variability in ten species of schooling, reef-resident planktivores. Site 4 (20m) was no longer significant when these species were removed from the analyses. MDS plots of fish abundances between years at all 10m and 20m sites at Aldabra Atoll (Fig. 4)and single sites at Assomption (Fig. 5), Astove (Fig.

Discussion

Aldabra Atoll and Assomption, Astove and St. Pierre Islands all suffered massive and extensive bleaching-related losses of live coral habitat in 1998. However, the pre-bleaching reef fish communities at these four locations seem to persist long-term post-bleaching, as demonstrated by the lack of directional changes between years in the MDS plots. Many studies have documented the strong associations between live coral habitat and reef fishes (review in Wilson et al. 2006), as well as the high variability in reef fish communities (review in Holbrook et al. 2006). The responses of reef fishes found in this study leads to an intriguing question of why directional changes in these fish communities have not occurred during eight years following the bleaching event in which there were two location-specific habitat phase-shifts. Change is used here with the caveat of "detectable within the bounds of the methodology used by AMP". There are likely many factors contributing to the lack of change in the assessed reef fish assemblages. We discuss some here in relation to the concept of pushing the ecosystems to their "tipping point", beyond which reduced resilience can lead to change and undesirable phase shifts (Littler and Littler 2007).

The four systems under study were rich in corals and fishes prior to the 1998 bleaching impacts and coral richness could have influenced the apparent continued-stability responses of the reef fish communities to the single-event loss of up to 50% of the live coral habitat. That is, the 1998 event was not a catastrophic-enough level of decline in live coral in these rich systems to trigger change in the basic reef fish assemblages (after Holbrook et al. 2006).

At Aldabra Atoll the rapid habitat phase shift to *Rhytisma* could have ameliorated the loss of hard coral habitat by providing the modest recovery of the living coral on the reef that could enhance stability of the fish assemblage as noted by Holbrook et al. (2006). For *Rhytisma* to be a factor, it would have to provide an ecologically acceptable alternative to important habitat functions affecting the fish community structure that were likely reduced with the loss of hard coral. There is limited information on any direct habitat functions of soft corals for reef fishes, but there is the potential for indirect effects on the composition of reef fish assemblages through biotic interactions between soft corals and other organisms, including hard corals (Syms and Jones 2001). However, *Rhytisma* habitat was a factor only on Aldabra Atoll and not on the three islands that also had no directional changes in their post-bleaching fish communities. Determining if *Rhytisma* habitat had a positive or neutral, or maybe negative, affect on reef fish communities is beyond the scope of this study, leaving the habitat-function role of *Rhytisma* in this situation open for continued speculation.

The framework of erect dead coral provides reef habitat heterogeneity after bleaching disturbance, which is a major factor in reducing changes in the reef fish community (review in Wilson et al. 2006). However, erect dead coral has not registered as a major habitat at Aldabra Atoll or the other three locations, after showing initial decreases and then minimal percentage changes between years. This is more an artifact of the habitat surveys than a true measure of the presence or rate of deterioration of the dead coral framework. The increases in other biotic habitats, such as the growth of *Rhytisma* at Aldabra Atoll, *Halimeda* at Assomption, and encrusting algae at all four locations, have both covered the surface of coral framework and likely added to its' stability and durability. Complex dead coral habitats can provide the habitat functions required by reef fishes with facultative or no relationships with live coral (Bellwood et al. 2006, Holbrook et al. 2006, Graham et al. 2007). Only those fishes with specific dependence on live hard corals will show marked responses to loss of this habitat (Pratchett et al. 2006, Feary et al. 2007) and there were few of these species in the systems surveyed in this study (Buckley et al. 2005).

The trophic plasticity of the fishes on these post-bleaching habitats would be an important factor in the resilience of the fish assemblages over time. If all but the few coral obligate fishes had the ecological versatility to adapt to any changes in prey resource availability caused by the reductions in live hard coral, then these trophic-functional groups of reef fishes would persist even though there was some variability at the species level (see Spalding and Jarvis 2002).

Direct anthropogenic disturbances to reef fishes can have a greater influence on fish assemblages than bleaching-related losses of live coral habitat (McClanahan 2006). Also, these two processes acting in synergy can confound determinations of the natural responses of the reef fishes to coral habitat impacts. Aldabra Atoll was protected from all but minimal anthropogenic disturbances primarily from local subsistence fishing (Pistorius and Taylor 2009) and the pre-bleaching fish assemblage persisted over time. Similar patterns at neighboring unprotected islands suggest any anthropogenic impacts at these locations were below the thresholds affecting local reef-resident species.

The coral habitat in the huge lagoon at Aldabra Atoll received minimal impacts from the 1998 bleaching event (Stobart et al. 2002). This physically protected area is thought to function as a sanctuary for reproductive-age adults and as a nursery area for many reef fishes (AMP, unpublished data). This reproductive potential could provide a steady supply of larval and juvenile fishes for the outer reefs at Aldabra, as well as to islands in the surrounding region. Even at moderate levels, this output could possibly override any bleaching-related loss of local and regional reproductive potential. This is an area of future research by AMP.

The findings here support earlier assessments that the reef fishes at Aldabra Atoll continue to reflect pre-bleaching reef fish community structure, and abundance changes appear to represent the ecology of the "natural" system (Downing et al. 2005, Downing et al. 2006). The pre-bleaching reef fish communities also appear to persist at Assomption, Astove and St. Pierre Islands. It is apparent that the 1998 bleaching impact was not a catastrophic disturbance to these systems. If there was any synergy between the loss of live coral and other post-bleaching biotic or habitat factors, it does not appear to have pushed the ecosystems past their tipping points, initiating directional changes in the associated reef fish assemblages.

Acknowledgement
We thank the Fondation d'Enterprise Total for their part in funding this project. Funding in early years was also provided by CORDIO. The Seychelles Islands Foundation has offered essential support to the AMP since its foundation, and we particularly thank Executive Director Lindsay Chong-Seng, Executive Officer Ronny Renaud, Chief Executive Officer Dr Frauke Fleischer-Dogley and SIF chairman M. Lostau Lalanne for their support. We also thank Rolph Payet, Seychelles Ministry of Environment and Transport and Patrick Lablache, Ministry of Land Use and Habitat. The TUI AG group, British Airways Assisting Conservation, Dahm International, PADI Project Aware, Profitability Business Simulations, S.Y. Thalassi, Borg Warner and many anonymous donors have also given their kind support. Finally, Tom Spencer is thanked for his encouragement and advice at the inception of AMP. Finally thanks to the Save Our Seas Foundation for funding attendance of the 11th ICRS.

Abstract. This study aims to determine the damage caused by the 2005 hurricanes "Emily" and "Wilma" on the landscape structure of the Parque Nacional Arrecifes de Cozumel (PNAC), México. We conducted samplings at six reefs located in the PNAC during May 2005 and May 2007. At each reef, six 30-m point-intercept transects were run parallel to the coast. The bottom elements that were quantified were coral, sponges, macro algae, coral with recent death, rock and sand. Landscape structure was quantified with the Pielou´s evenness index (J´), and changes were evaluated with non-metric multi-dimensional scaling (NMDS) and the Bray-Curtis similarity coefficient. The results show a significant decrease in the percentage of live cover, and an increase in the percentage of sand and rock. Corals were the most affected group decreasing from 24% to 10% in cover after the two hurricanes; fortunately, cover has increased to 16% by May 2007. Significant differences were found in the landscape evenness, being lower in July 2005($F_{5,210}$= 14.94, P=0.00),; the high similarity of J´ between May 2005 and May 2007 indicates a clear trend of recovery in the reefs. The NMDS show that the two hurricanes affected Cozumel reefs with varying intensity, with "Wilma" having an impact four times higher than "Emily".

Key words: Hurricanes, reefs, algae, Scleractinian coral, sponge, sand, rock.

Introduction

Tropical storms are usually seen as natural disturbances that modify the structure of biotic assemblages in short time periods on tropical reefs (Woodley et al. 1981). However, these phenomena also modify the abiotic components of the landscape and therefore their influence on biodiversity is not just immediate but can last for many years (Michener et al. 1997).

The most developed reefs in Mexico are in the Caribbean (Jordan-Dahlgren 1993). These reefs represent the northernmost part of the Mesoamerican Reef, recognized as one of the most important reef systems in the world (Almada-Villela et al. 2003). In this region, the island of Cozumel represents a key ecological reserve because of the high species richness and the complexity of the ecosystem (Jordán-Dahlgren and Rodríguez-Martínez 2003; Fig. 1). Cozumel reefs are also highly important for the socio-economics of the region, since they attract thousands of divers and snorkelers by its spectacular underwater spots (Spalding 2004).

During 2005, the island of Cozumel suffered the impact of two of the strongest hurricanes in record, "Emily" and "Wilma" (Alvarez - Filip 2007). The first one hit the coast of the Yucatan Peninsula on July 17, with sustained winds of 215 km/h and gusts up to 260 km/h. The eye of the hurricane passed about 5 km from the southern tip of Cozumel, moving in southeasterly direction, so the intensity of the winds diminished to the north of the island. A few months later (October 21 to 24), "Wilma" affected the island. This is the strongest hurricane recorded in the Atlantic Ocean (the tenth globally), with the lowest atmospheric pressure recorded historically in the Western Hemisphere (882 millibars at sea level, Nava-Alvarez 2005). The hurricane eye (63 km in diameter) moved across Cozumel with sustained winds of 220 km/h and gusts of more than 300 km/h, and moved very slowly, at a speed of less than 5 km/h, heading north-northwest (Alvarez-Filip 2007).

The hurricanes not only caused high mortality of benthic species but also moved away enormous volumes of sand and left large areas of bare rock, devoid of colonizers (Alvarez-Filip and Gil 2006).

Considering the strength and extent of the perturbation, the relevance of the reefs, and the need for a systematic evaluation of the effects on the entire ecosystem, our objective was to determine the effects of "Emily" and "Wilma" and the subsequent changes on the landscape structure of the reefs within the limits of the marine protected area of the Parque Nacional Arrecifes de Cozumel (PNAC). We observed a remarkable decline in all the biotic components and a considerably increase on bare rock after the hurricanes. During the 2 following years the reefs started to recovery, however, the general landscape may not be returning to its original state.

Material and Methods

Study area. Cozumel (Fig 1) covers an area of 647.33 km^2, is located approximately 22km from coast of Quintana Roo. The island is occasionally affected by hurricanes in summer and fall (June to November), although August and September are the months with more intense activity. The southwestern coast of the island has been under official protection since 1980; but was in 1996 when Natural Protected Area decree (INE 1998). The Parque Nacional Arrecifes de Cozumel (PNAC), which is the official name, goes from the north end of Paraiso reef (20º 35´ 22 N, 86º 43´ 46 W) to the southernmost tip of the island, and then continues north as far as Punta Chiqueros in the windward side (20º 16´ 11 N, 86º 59´ 26 W; Fig. 1).

Field Work. We conducted seven visits to the area from May 2005 to May 2007. In each period we surveyed a total of six reef (Fig. 1), and a total of 36 transects were done per visit (six at each reef) using SCUBA equipment. and at a depth of 15 m.

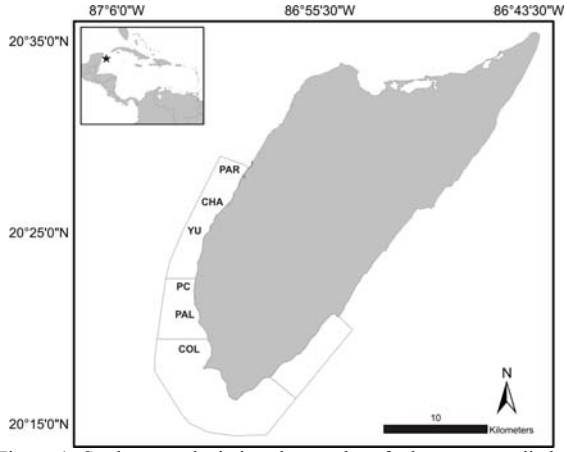

Figure 1: Study area, depicting the coral reefs that were studied at Cozumel Island. PA= Paraiso, CHA= Chanlana´ab, YU= Yucab, PC= Paso del Cedral, PAL= Palancar, COL= Colombia. Continuous line delimits the polygon of the Parque Nacional Arrecifes de Cozumel.

We used the point interception method to evaluate the components of the benthic substrate. The procedure consisted of placing a 30 m-long transect parallel to the coast and recording the type of bottom found directly below points signaled every 25 cm (120 sampling points in total per transect; Almada-Villela et al. 2003), and calculating percentage of bottom cover by each one. Then, the information was systematized and classified in ten major groups: bare rock, sand, dead coral, fleshy macroalgae, sponges, octocorals, hexacorals, turf algae, cyanophytes and coralline algae.

Statistical analysis. Using the percentage of cover of each bottom component, we calculated the Shannon-Wiener diversity index (base 10) and Pielou´s evenness index for each transect, reef and season. These indicators are recognized as among the best to characterize the complexity of the landscape (Jongman et al. 1995; Magurran 2003). Next, the level of change in the reef background among sampling dates was determined with analysis of variance, after confirming homoscedasticity and normality of the data (Zar 1999). Finally, we computed the similarity along landscape compositions in the different samplings with the Bray-Curtis similarity coefficient, and mapped the full information with a non-metric multidimensional scaling (NMDS; Martínez and Adarraga 2001).

Results

Abiotic components. In May 2005 the cover of sand and rock recorded together was 26% in the six sites. During July 2005, when the island received the impact of "Emily", the situation remained very similar, although the amount of rock increased as a result of sediment transport to deeper area. However, in the sampling after "Wilma" and the next one (May 2006) the bare rock was by far the dominant bottom type (~ 40% in average). In the last two visits, the rock decreased its percentage cover to about 25% and remained around that figure to the end of the study. Comparatively the amount of sand was much more stable; it actually decreased after "Wilma" but double its average by the following May (2006), and increased gradually since. Dead coral has been a minor component in the entire study, and had higher values after "Emily". By the last three censuses, dead coral cover was remarkably low, probably because most diseased or damaged colonies were broken and transported away from the reef by the hurricanes.

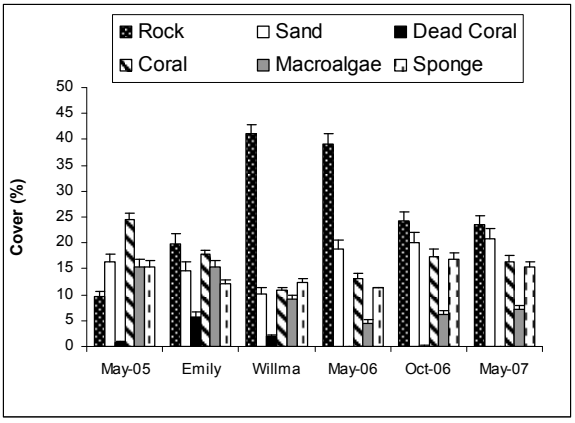

Figure 2: Average cover of the most common bottom types at Cozumel reefs, between May 2005 and May 2007.

Biotic elements. In the case of sponges, their abundance first diminished because of the mass mortality caused by the hurricanes (Alvarez-Filip and Gil 2006), but there was a considerable rebound by May 2007 (Fig. 2). There were significant differences between seasons ($F_{5, 210}$= 41.456, p< 0.0001), caused by the low average found in May 2006, immediately after the hurricanes.

The behavior of the coral abundance at Cozumel was similar to that of the sponges, and we also depicted significant differences between seasons ($F_{5, 210}$= 16.86, p< 0.0001), although in this case were caused by the high cover in May and July 2006. Afterwards the average did not differ (fluctuating between 8% and 12%), an indication of a certain stability and long-term effects of the hurricanes on this group (Fig. 2).

The macroalgae behaved in the same way that corals ($F_{5, 210}$= 22,971, p< 0.0001) and the significative differences separated the higher values from May 2005 and July 2005 (after "Emily"), to the remainder. It is also apparent that the declining trend continued until spring 2006, and from then on the algal cover increased but still is much lower than the original.

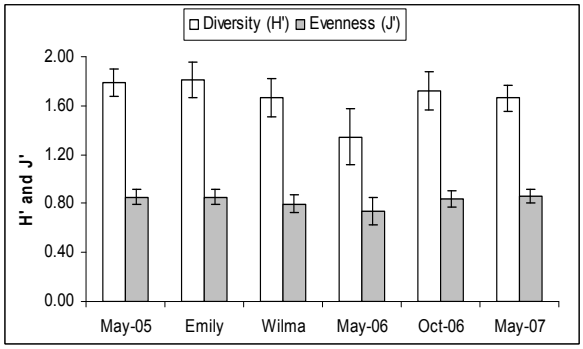

Figure 3: Diversity and evenness of the reef landscape at Cozumel Island between May 2005 and May 2007.

Landscape approach. Diversity and evenness of the landscape components was very stable at Cozumel (Fig. 3), although in both cases a clear and significant decrease occurred in May 2006 from the rest of samplings. Finally, the NMDS (Fig. 4) shows three stages in reef landscape composition between 2005 and 2007: first, the data from May 2005 and the first hurricane ("Emily"), then "Wilma" and the ensuing sampling in spring 2006, and finally the last visits (October 2006 and May 2007).

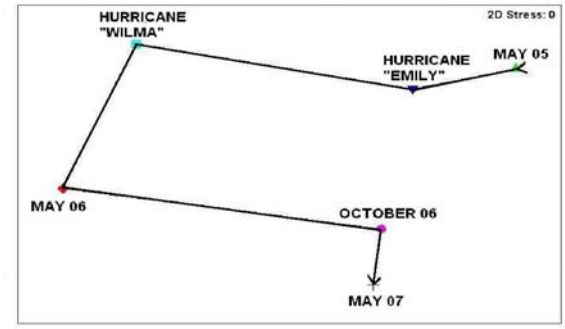

Figure 4: Non metric dimensional scaling comparing the bottom composition at the six sampling seasons (May 2005 to May 2007).

Discussion

This paper is one of the first to analyze the effects of hurricanes from a landscape perspective in México. We consider that this was the correct approach since the passage of hurricanes "Emily" and "Wilma" affected not only the live elements but also the abiotic ones. Then, by taking a more inclusive view we may have a better image of the long-lasting consequences to the composition and function of the system that if only we focus on specific taxa.

As shown by Fig. 2, during the study period we testified a major shift in the proportions of components of the substrate, directly caused by the incidence of two hurricanes in 2005. In general, there was a remarkable increase of the amount of bare rock and a decline in all biotic components, and probably both events were due to the movement of sand across the reef, and its eventual discharge to the slope (Alvarez-Filip and Gil 2006). A similar situation was faced by other locations along the Mexican Caribbean coast, and more specifically at Cancún (McField et al 2008), but the long term results differed remarkably. At Cancún the lack of reefs and limited generation of new sand caused a net deficit and the need to carry new sand to the beach, taken from deep areas, while at Cozumel the coral barrier naturally supported enough material so the amount of sand in the reef soon returned to normality (Fig. 2).

The loss of sand can have important consequences at Cozumel; water clarity diminished a lot after the

hurricanes because of the floating sand grains (LAF personal observations), and that may have altered the metabolism of the zooxanthellae, decreasing in turn the amount of food for corals and the rest of the community, and probably affecting the reproductive success of scleractinians (Chavez et al. 2003; Fabricius 2005). In addition, Alvarez-Filip (2007) indicated that as the large amount of sand moved to the barrier reef and surrounding areas in 2005 left a sizeable area of new substrate, it was to be expected that many new areas were available for colonization. If this is the case, we can expect a high incidence or benthic recruitment in years to come. As the data in Figure 2 show, sponges and corals may have been responding to this opportunity, but nevertheless their slow growth rate forces that the process should take many years (McMurray et al. 2008). This hypothesis checks well with Fenner (1991) observation that after Hurricane "Gilbert", it was expected at least 10 years for recovery of Cozumel reefs.

Many studies have documented changes severe damage to coral colonies and populations due to the behavior of the waves and sea currents during a hurricane (Woodley et al. 1981; Rogers 1993; Kjerfve et al. 1996), and a consequent change in the composition of the biotic components (Done 1992; Bythell et al. 1993; Bahena et al. 2000). At Cozumel, before 2005 were clear differences in coral cover among reefs, but after 2005 we noticed an homogenization of abundance all over the national park (Millet-Encalada et al. 2007). In general this took place because differential mortality concentrated in the two main genres (*Agaricia* and *Porites*), which because of its morphology are much more prone to mechanical damage.

The general trend in the coverage of the sponge was a reduction after 2006 (Fig. 2). This was expected considering fragile structure of these animals that can be easily damaged by the abrasion caused by sediment movement, and to excessively high speeds in water flow (Done 1992; Fenner 1991). However it is important to note that many broken colonies are recovering its size using cellular growth (Stoddart 1974), and probably the cover will increase faster that anticipated by asexual recruitment.

As for the percentage of macroalgae found, this was very variable during the study but fortunately cover was never too high; this means that there is no indication of a phase shift due to the opening of colonization spaces in the reef. Very probably the control of algal proliferation was exerted by urchins but mostly, by herbivorous fishes, which numbers are higher than 2 fishes/m^2 (Díaz-Ruiz and Aguirre León 1993; Lozano Alvarez et al. 2007). Considering this information we support the idea that Cozumel reefs can still be considered as healthy, even when human use is very high (Rioja-Nieto and Sheppard 2008).

In this study we applied diversity and evenness indices (H' and J') to describe the complexity of the reef landscape in the study region. The data showed a clear decrease in May 2006 which reflects the post-hurricane response to two major perturbations, however, both indices rapidly return to the original figure and by the end of the study there was no statistical difference in the indicators. This result may be the best indication of the reef resilience.

Although our data show that Cozumel reefs resisted well the effect of the hurricanes, there are still changes of notice. The NMDS clearly shows that between 2005 and 2007 there have been three distinct stages in reef succession: May to July 2005, late 2005 and early 2006, and the last two samplings (Fig, 3). The fact that the arrow did not return to the original position in the graph remarks that the reefs are showing signs of recovery, but are not "returning" to its original condition; a more accurate view is that the landscape is in dynamic equilibrium, and we need more years to actually confirm what direction is taking.

In conclusion, the effects of two major hurricanes on the landscape diversity of Cozumel reefs were clear, but in a very short time span the animal and plant communities as well as the abiotic environment, seem to be regaining their position. It is probable that if no other perturbation of this caliber occurs, we can assess a complete recovery of the ecosystem. However, the situation may not be so adequate in the near future considering the projected increase in anthropogenic pressures (especially coastal development) for the entire Mexican Caribbean. It is vital to keep a proactive position for management and preview what problems can occur if the number of visitor keeps increasing, and also to continue monitoring and Before –After studies (Michener et al. 1997), fundamental to assess the long-term effects of these perturbations.

Population status of the urchin *Diadema antillarum* in the Florida Keys 25 years after the Caribbean mass mortality

M. Chiappone[1], L.M. Rutten[1], D.W. Swanson[2], S.L. Miller[1]

1) University of North Carolina-Wilmington, CMS, 515 Caribbean Drive, Key Largo, FL 30337, USA
2) University of Miami, RSMAS-MBF, 4600 Rickenbacker Causeway, Miami, FL 33149, USA

Abstract. The 1983-84 Caribbean-wide mortality of the urchin *Diadema antillarum* Philippi was followed by a second mortality event in the Florida Keys in 1991. The demise of this once ubiquitous herbivore is one factor contributing to wider Caribbean reef change during the past 25 years. Over an 8-year period from 1999-2007, we examined densities and test sizes of *D. antillarum* at 786 sites from the northern extent of the Florida Reef Tract to the Dry Tortugas, including two National Parks and the Florida Keys National Marine Sanctuary. Visual surveys along belt transects were used to enumerate individuals and test sizes in a two-stage stratified random sampling design that incorporated cross-shelf benthic habitats, geographic regions, and no-fishing management zones. While pre-1983 densities were as high as 5 individuals/m^2, surveys since 1999 from < 1 m to 27 m depth show that current densities are still well below 1 individual/m^2. During seven different annual sampling periods, the maximum site-level density was only 0.33 individuals/m^2, with the highest densities of larger (> 5 cm test diameter) individuals reported from only a few locations. The relative contributions of larval survivorship, predation, suitable recruitment sites, and reduced fertilization success to *Diadema* recovery are still largely unknown.

Key words: Benthic, *Diadema*, marine protected area, stratified sampling, urchin.

Introduction

The 1983-84 Caribbean-wide mass mortality of the long-spined sea urchin *Diadema antillarum* represents one of the most spatially expansive and prolonged disturbances to reef ecosystems in the region (Carpenter 1988; Lessios 1988, 2005). Prior to the mass mortality event, *D. antillarum* attained high (>20 per m^2) densities in many Caribbean reef areas (Lessios 1988), but urchin abundances declined by several orders of magnitude and have remained in this state over two decades later (Lessios 2005; Weil et al. 2005; Debrot and Nagelkerken 2006). Together with physical impacts from storms, coral disease outbreaks, and severe bleaching episodes (Gardner et al. 2003), the reduction in urchin densities has had severe consequences in terms of coral-algal dominance patterns (Carpenter 1988; Lessios 1988).

In the Florida Keys, the few historical data available prior to 1983-84 indicate that *Diadema antillarum* densities were lower (up to 4-5 per m^2) (Kier and Grant 1965; Bauer 1976, 1980). However, still a general trend of increased algal cover was apparent after the urchin mortality at several Florida Keys reefs (Jaap et al. 1988; Porter and Meier 1992). Seven years after the 1983-84 event, a second disease event in the Florida Keys, after initially modest recovery to 0.30-0.58 individuals/m^2, once again depressed *D. antillarum* densities to < 0.01 individuals/m^2 (Forcucci 1994). Large-scale surveys of urchin densities across the south Florida during 1999-2001 confirmed this pattern of poor recovery (Chiappone et al. 2001, 2002).

Since the mass mortality, limited to moderate recovery in *Diadema antillarum* populations has been reported in some Caribbean reef areas (Lessios 2005; Carpenter and Edmunds 2006; Debrot and Nagelkerken 2006), but this has not occurred in the Florida Keys (Chiappone et al. 2002; Lazar et al. 2005). It is anticipated that *D. antillarum* recovery will help to promote coral recruitment and a return to pre-mortality baseline reef conditions (Carpenter and Edmunds 2006; Macia et al. 2007; Myhre and Acevedo-Gutierrez 2007). There is particular interest in the spatial and temporal patterns of recovery in the Florida Keys, as there are expectations that urchin recovery will perhaps help to reverse the trend in seaweed expansion and concurrent declines in reef-building corals. In addition, the slow and incomplete recovery of this urchin raises the question of factors limiting population recovery (Miller et al. in press).

Since 1999, we have conducted intermittent, large-scale surveys of urchin density and size structure in a diversity of habitats across the south Florida shelf encompassing hundreds of sites. This short communication describes the population status of *Diadema antillarum* as of 2007 along ~200 km of the

Florida Reef Tract, but also provides a temporal comparison of population densities and size structure since 1999 in both the Florida Keys and Dry Tortugas regions. These results are a follow-up to previous reports on the population status of urchins in the Florida Keys (Chiappone et al. 2001, 2002) and are part of an ongoing assessment and monitoring program to evaluate large-scale ecological patterns in community structure and the responses of small reef areas to protection from fishing pressure (Miller et al. 2002).

Material and Methods

The Florida Keys are an archipelago of limestone islands stretching more than 360 km from Key Biscayne to the Dry Tortugas. Along the seaward edge of the south Florida shelf is the reef tract, a semi-continuous series of offshore bank-barrier reefs interspersed with sand, rubble, and low-relief hard-bottom (Shinn et al. 1989). Between the islands of the Florida Keys and the reef tract is Hawk Channel, a V-shaped basin (5-12 m depth) dominated by sand, seagrasses, and patch reefs (FDEP 1998). Coral reef distribution and community structure in the Florida Keys reflect exchange processes between Florida Bay and the Atlantic Ocean affected by the size and orientation of the Pleistocene islands and the proximity of the Florida Current to the platform margin (Shinn et al. 1989).

During 1999-2007, a series of research expeditions were carried out to quantify, among other variables, urchin density and size distribution patterns across the south Florida shelf. A two-stage, stratified random sampling approach was used to derive mean density estimates for urchins at multiple spatial scales throughout the Florida Keys, following similar procedures outlined in Cochran (1977) and modified for our coral reef benthic surveys (Miller et al. 2002; Smith et al. in press). Surveys were carried out in the Florida Keys, excluding the Dry Tortugas, in 1999-2001 and 2005-07, and in the Dry Tortugas during 2000 and 2006 (Figs. 1-2). The sampling domain was partitioned by habitat type using available bathymetry and benthic mapping data (FDEP 1998). The habitat classification scheme accounted for features that correlate with benthic fauna distributions, including cross-shelf position, topographic complexity, and the proportion of sand interspersed among hard-bottom structures. Additional stratification variables included regional location and management zones, the results of which are reported elsewhere. Map resolution was such that the survey domain was divided into a grid with individual cells of size 200 m by 200 m (40,000 m^2) that defined unique habitat classes. Table 1 provides the classification system used during the 2007 surveys at 235 sites in the Florida Keys.

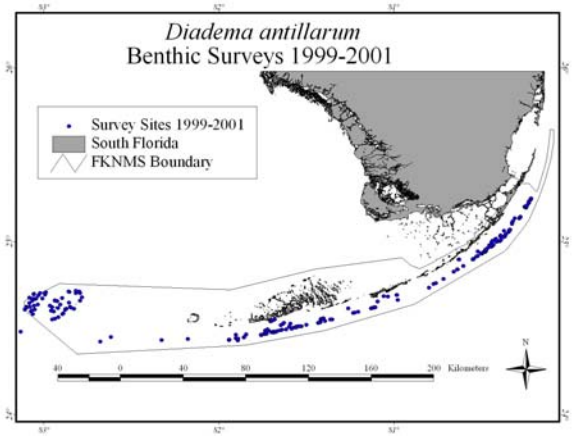

Figure 1: *Diadema* urchin survey sites in the Florida Keys National Marine Sanctuary (FKNMS) sampled during 1999-2001.

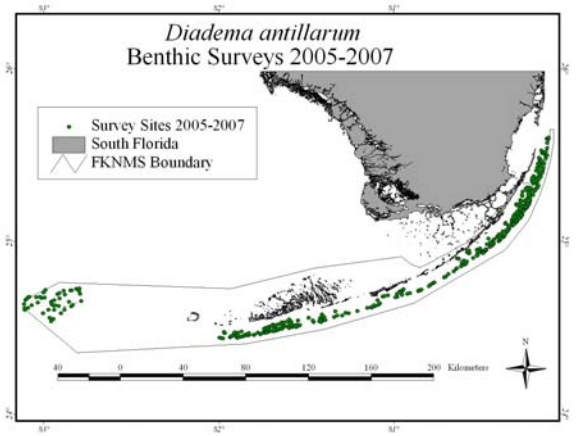

Figure 2: *Diadema* urchin survey sites in the Florida Keys National Marine Sanctuary (FKNMS) sampled during 2005-07.

During each sampling mission, four random sampling points were generated in a GIS and were located in the field using a differential global positional receiver. During 1999-2001, paired 10 m or 25 m transects, depending on the site area, were deployed at each of the four sampling points. A 0.4 m scale bar was used to sample along both transect sides for the number and test diameter of urchins. During 2005-07, four 15-m x 1 m belt transects were sampled per site. Urchin density calculations were calculated for each site and for each stratum, consisting of combinations of habitat, regional location, and management zone. Data reported herein emphasize habitat-related patterns in density from the 2007 surveys, but also temporal comparisons between 1999-2001 and 2005-2007. Statistical comparisons of mean densities were accomplished by computing confidence intervals (CI) based on the equation: CI = mean $\pm$ $t_{[\alpha,\ df]}$ *standard error. Standard errors were estimated by the two-stage, stratified random sampling design (Cochran 1977) and confidence intervals were adjusted for multiple comparisons

using the Bonferroni procedure. The experiment-wise error rate was held at $\alpha = 0.05$ and the comparison-wise error rate was adjusted based on the number of multiple comparisons as follows: comparison-wise error rate = α/c, where $c = k(k-1)/2$ and k = number of categories (e.g. habitat classes).

Table 1: Characteristics of *Diadema* urchin survey sites in the Florida Keys sampled during 2007. Available sites reflect the number of 200 m x 200 m cells containing particular habitat types based upon FDEP (1998) mapping data

Habitat	Depth (m)	Sites (% effort)	Sites available

Results

Results presented herein detail *Diadema antillarum* population density and size structure based upon 2007 surveys, as well as temporal comparisons encompassing 1999 through 2007. Surveys of 235 sites from the northern Florida Reef Tract to SW of Key West during 2007 yielded relatively low densities, but slightly larger test sizes compared to previous sampling periods. A total of 299 individuals were recorded, with individuals distributed among all nine habitats sampled. The maximum site-level density was 0.267 individuals/m^2 from an upper Florida Keys offshore patch reef. Relative to previous years, an appreciable increase was apparent in the number of sites where *D. antillarum* was found and a general trend towards larger test sizes. Densities were greatest on offshore patch reef and high-relief spur and groove reefs (Fig. 3). However, habitat-level densities were so low that, despite the relatively large sample size, the only significant difference detected was between the offshore patch reef and deeper hard-bottom habitats ($P < 0.0018$, Bonferroni-adjusted α). Of the 299 *D. antillarum* recorded, test sizes ranged from 0.3-10.0 cm, with a mean ± 1 SE test size of 3.6 ± 0.1 cm. The test size distribution, in contrast to previous years, included a relatively large proportion (~33%) of individuals > 5 cm TD (Fig. 3).

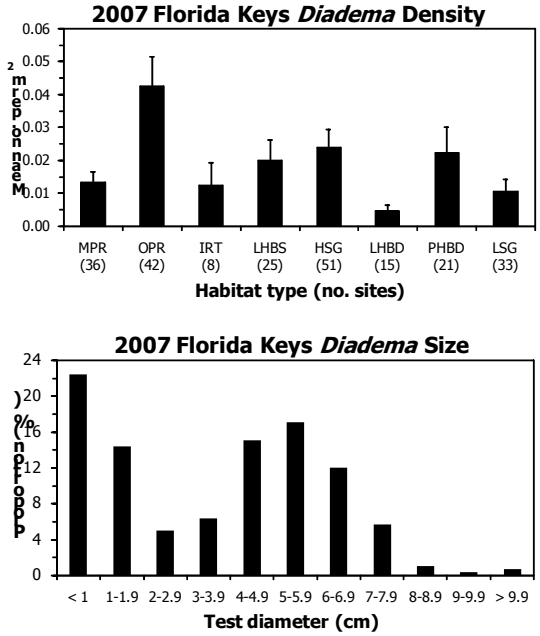

Figure 3: Mean *Diadema antillarum* densities by habitat (top) and test size distribution (bottom) from surveys of 299 individuals at 235 Florida Keys sites during 2007. Error bars are +1 SE and numbers in parentheses on the x-axis (top) are the number of sites sampled in each habitat. See Table 1 for habitat abbreviations.

Table 2 summarizes the temporal in *Diadema antillarum* density and size structure during two time periods in the Florida Keys and Dry Tortugas. In the Florida Keys, a greater proportion of sites yielded no *D. antillarum* in 1999-2001 (75%) compared to 2005-07 (62%). However, very few sites in either time period (≤ 1%) yielded densities greater than 0.2 individuals/m^2. The range in test size, the maximum test size, and the mean test size has increased since 1999-2001. The largest apparent changes are the ~42% increase in mean test size and the proportion of urchins larger than 5 cm TD in 2005-07 (32%) compared to 1999-2001 (9%).

For the Dry Tortugas region, including both shallower (< 15 m) habitats within the National Park and deeper (> 15 m) habitats on the Tortugas Bank, there are temporal similarities in density distribution, but differences in size distribution with the rest of the Florida Keys (Table 2). A greater proportion of sites yielded no individuals in 2000 (59%) compared to 2006 (44%), and very few sites in either time period (< 5%) yielded densities greater than 0.2 individuals/m^2. In terms of size structure, the most notable differences between the two time periods were the dramatic (58%) decrease in mean test size, as well as 28% change in the proportion of

individuals larger than 5 cm TD, a pattern opposite to that documented in the rest of the study area.

Table 2: Temporal summary of *Diadema antillarum* density and size structure in the Florida Keys and Dry Tortugas regions during 1999-2001 and 2005-07. Site-level densities are the number (proportion) of sites with a given mean density value

Discussion

Large-scale surveys encompassing hundreds of sites across the south Florida shelf since 1999 indicate that the *Diadema antillarum* population exists at densities well below values reported before the two mortality events in 1983-84 and 1991 (Kier and Grant 1965; Bauer 1980; Forcucci 1994). For the Florida Keys there has been an increase the proportion of sites with *D. antillarum* present, as well an increase in mean test size, with a greater proportion of larger individuals in the population. Earlier reports and recent observations indicate that other urchin species show density and habitat distribution patterns similar to pre-1983 observations, indicating that other species have not compensated for the loss of *D. antillarum* (Chiappone et al. 2002).

In the Dry Tortugas, the past six years have witnessed a decline in average size, possibly indicative of a recruitment event, perhaps in 2005, or poor survivorship to larger sizes, or both. It is noteworthy that Dry Tortugas surveys conducted in 2006 followed a very active tropical cyclone season in 2005, where several named storms passed directly over or in close proximity to the Dry Tortugas. In areas with relatively high (> 0.1 individuals/m^2) and larger (> 5 cm TD) *Diadema antillarum*, there are obvious effects of grazing on the substratum, particularly the removal of turf and macroalgae and exposure of reef rock (Chiappone et al. 2001). It remains unclear at this time whether increasing urchin densities and sizes will lead to other changes such as increased coral recruitment.

The very slow and prolonged recovery in the Florida Keys, especially compared to several recent studies in other Caribbean reef areas, raises several questions pertaining to the possible factors inhibiting recovery. Lessios (1988) and others have discussed the merits of hypotheses concerning population recovery, among them poor larval survivorship, lack of adult conspecifics and hence protection from predators, suitable recruitment sites, and inter-specific competition. The sources of urchin larvae to the south Florida shelf are not known, but may include both local and regional sources (Lee et al. 1994). Nonetheless, it is apparent that *D. antillarum* have continually recruited to benthic habitats, even after the 1991 mortality event (Chiappone et al. 2002). A recent study of *D. antillarum* larval settlement rates in the Florida Keys, however, indicate that low larval supply may be one factor limiting recovery (Miller et al. in press). The predominance of relatively small test sizes from 1999-2007 indicate post-settlement recruits have poor survivorship, perhaps due to predation pressure or physical disturbance from storms. Because *D. antillarum* was historically significant as a grazer it will be important to monitor its change in abundance and size structure over time, as well as the possible effects on benthic community structure in the Florida Keys.

Acknowledgement

Financial support was provided by the Florida Keys National Marine Sanctuary, NOAA's Coral Reef Conservation Program, Emerson Associates International and NURC/UNCW. The authors

thank O. Rutten, B. Keller, R. Curry, New World Expeditions, the crew of the M/V *Spree*, The Nature Conservancy, Quiescence Diving Services, A&B Marina, Lost Reef Adventures, Cudjoe Gardens Marina, and Hall's Diving Center. This effort would not have been possible without B. Altmeir, S.G. Smith and J.S. Ault. Research was conducted under National Marine Sanctuary Permit FKNMS-074-98 and National Park Service Permit BISC-2005-SCI-0039.

Coral Reef Monitoring for the Organization of Eastern Caribbean States (OECS) and Tobago

J McGann2, M. Creary[1]

1) Centre for Marine Sciences, University of the West Indies, Kingston 7, Jamaica W.I.
2) MACC Project, Caribbean Community Climate Change Centre, P.O. Box 563, Belmopan, Belize

Abstract. The objective of this project was to expand the coral reef monitoring programme started under the CPACC (Caribbean Planning for Global Climate Change) Project to the countries of the Eastern Caribbean. The Centre for Marine Sciences (CMS) of the University of the West Indies (UWI) Jamaica was contracted by the MACC (Mainstreaming Adaptation to Climate Change) Project to oversee this process. Sixteen participants from seven Eastern Caribbean countries (Antigua & Barbuda, Dominica, Grenada, St Kitts & Nevis, Saint Lucia, St Vincent & the Grenadines and Tobago) were trained in the coral reef video monitoring protocol developed under CPACC in Saint Lucia during September 2007. Following the training, each country selected a monitoring site and monitoring was conducted (during the period September to April 2008) at these sites under the supervision of resources persons from the CMS. The videotapes were processed and analyzed at the CMS. This paper will discuss the results of the monitoring exercise for each of the countries and will highlight the challenges encountered in establishing a regional monitoring programme that meets the needs of the participating countries

Key words: Eastern Caribbean, coral monitoring, video monitoring, climate change

Introduction

The Caribbean Community Climate Change Centre (CCCCC) was established by regional governments to coordinate the Caribbean's response to climate change. One of the projects being executed by the CCCCC is the Mainstreaming Adaptation to Climate Change (MACC) Project which aims to mainstream adaptation to climate change into national development planning through technical support and capacity building. Included in the capacity building programme was the strengthening of the climate and coral reef monitoring networks in the region.

The Centre for Marine Sciences (CMS) under a Memorandum of Understanding with the CCCCC for MACC Project was tasked with leading the coordination and expansion of the regional coral reef monitoring programme to the OECS (Antigua & Barbuda, Dominica, Grenada, St Kitts & Nevis, Saint Lucia, St Vincent & the Grenadines) and Tobago (Fig. 1). This expansion follows up on the recommendations made at the conclusion of the Caribbean Planning for Adaptation to Global Climate Change (CPACC) project based on pilot studies carried out in The Bahamas Belize and Jamaica (Lawrence & Edwards, 2001).

This monitoring programme was implemented by providing technical support in the areas of training, monitoring, data analysis and report preparation. The data collected and reported on in this study is intended to represent the start of a coral reef monitoring programme for the OECS and Tobago which will assist in documenting the changes taking place on the coral reefs over time and will attempt to determine the reasons for the observed changes.

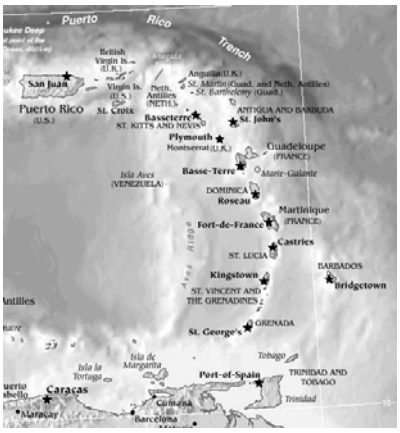

Figure 1: Map of the Eastern Caribbean showing the location of the seven countries (Antigua & Barbuda, Dominica, Grenada, St Kitts & Nevis, Saint Lucia, St Vincent & the Grenadines and Tobago) took part in the coral reef monitoring programme.

Methodology

Training

Training took place during the period September 10-13, 2007 in St Lucia and involved 16 participants from 7 countries. The participants were trained in the CPACC video monitoring protocol which involved site selection,

video monitoring, benthic substrate identification, data processing, data analysis and report preparation (Woodley 1999; Miller 2000; Miller and Roger 2002). At the end of the training workshop one set of video monitoring equipment, provided by the MACC project, was handed over to each of participating countries (Creary 2007).

Monitoring

Following the training workshop the participants returned to their respect countries and selected coral reef areas for monitoring (Operational Area) based on the guidelines outlined in the site selection protocol (Woodley, 1999) which took into consideration the use to which the data would be put, the peculiarities of the area and logistical constraints. Each country was required to establish 20 permanent transects, each 20m long, within the Operational Area selected.

The video monitoring method used was based on the Aronson method that was adapted by Jeff Miller (US GS Biological Division, USVI) for Component 5 of the CPACC project - *Coral Reef Monitoring for Climate Change Impact* (Miller 2000) and with additional modifications included in this monitoring exercise (Miller and Rogers 2002).

A resource person from the CMS led the local teams on the monitoring exercises. The high resolution video cameras provided for each country were used to video tape the individual 20m transects. Approximately 20 transects were recorded for each country. Monitoring was carried out during the period September to November 2007 for all the countries except for Antigua. Field works was started in Antigua during October 2007 (four transects were video taped) but was not completed due to several delays resulting from technical difficulties and poor weather conditions. Because of the long delay in completing the monitoring the entire exercise was repeated in April 2008. Both sets of data are presented in this paper. The monitoring dates along with the locations of the Operational Areas and monitoring sites are provided in Table 1.

Data processing and analysis

The videotapes were catalogued and delivered to the Caribbean Coastal Data Centre (CCDC) of the CMS for processing and analysis. A Sony Mini DV player, connected to a computer and using the Pinnacle Studio™ software, was used to capture non-overlapping adjacent images from the video tapes. The CPCe (Coral Point Count with Excel) programme (Kohler & Gill 2006) was used to randomly overlay 10 points on each image from which the benthic species or substrate category lying under each point was identified. Codes were entered directly into the associate Microsoft Excel spreadsheet which automatically generated statistical parameter for each species/substrate category (relative abundance, mean, standard deviation, standard error and the Shannon–Weaver diversity index).

Country /Dates	Operational Area/ Monitoring Site(s)
Antigua & Barbuda Oct 16, 2007 April 9-11, 2008	Little Bird Island
Dominica Nov 13- 15, 2007	Soufriere/Scott's Head Marine Reserve (SSMR) • Soufriere Pinnacle • Danglebens • Point Guignard • Champagne
Grenada Oct 31-Nov 2, 2007	Grand Anse reef system • Boss Reef • Middle Boss Reef • Bottom Boss Reef • Northern Exposure
St Kitts & Nevis Nov 4-9, 2007	Sandy Point • Paradise Reef

Tobago Oct 16-17, 2007	Speyside, Tobago • Japanese Gardens • Angel Reef

Table 1: Monitoring dates, Operational Areas and monitoring sites

Results

The results of the monitoring programme (Fig. 2 and 3) shows that the sites selected in each country had varying levels of coral cover ranging from 3.8% in Antigua (2008) to 29.2% in St Vincent & Grenadines. Dominica, Grenada, St Kitts and Saint Lucia had coral cover at about 10% while Tobago had 15.9%. Gorgonians were not very abundant in all the islands ranging from 1% to 3.6% with the exception of Tobago which had 16.8% cover. Sponges were also found in the highest abundance in Tobago with 21.2%, St Vincent had a little over half that amount with 12.1%, while St Kitts and Saint Lucia had 7.5% and 7.1% respectively. The other three countries had less than 4% gorgonians. The zoanthids represented a very small proportion of the benthic cover in all the countries ranging from 0% to 0.9%. Also not well represented were the coralline algae which ranged from 0% to 0.9% for all countries except Tobago which had a higher cover of 2.1%. Disease corals were observed in limited amounts in Antigua (2007), Dominica, St Kitts and St Vincent.

It was observed that for all the countries there was a high level of macroalgae combined with dead coral and

algae found on the reefs with Antigua (2007) having a combined value of 56.2%, Dominica having 66.6%, Grenada with the highest at 84.2% and St Kitts at 76.0%. Not unexpected was that Tobago (25.9%) and St Vincent (39.6%) exhibited the lowest levels of macroalgae combine with dead coral and algae, while Antigua – 2008 (44.9%) and Saint Lucia (44.4%) had intermediate levels.

During the monitoring exercise a total of 41 coral species were observed in addition to other unidentified coral species and coral juveniles. The most widely distributed species were *Diploria strigosa*, *Montastraea annularis, M. cavernosa, Porites astreoides* and *Siderastrea siderea,* which were found in all countries and *Agaricia agaricites, Meandrina meandrites, Millipora complanata* and *P. porities* which occurred in six of the seven countries. Just under half (18) of the species identified were found in only one or two countries, with the remaining 15 species occurring in 3-5 countries.

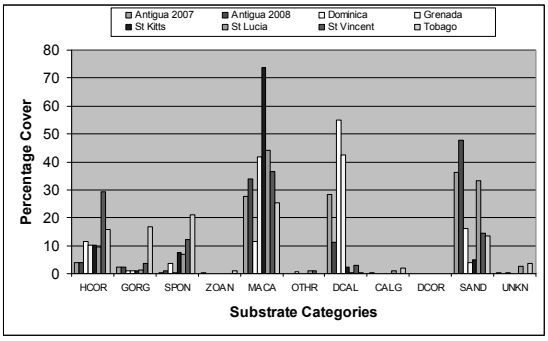

Figure 2: Graph illustrating the mean percentage cover for the different substrate categories found at the coral reefs sites in Antigua, Dominica, Grenada, St Kitts, Saint Lucia, St Vincent and Tobago monitored during the period September 2007 to April 2008. (Substrate categories: HCOR - Hard coral; GORG - Gorgonians; SPON – Sponge; ZOAN – Zoanthids; MACA– Macroalgae; OTHR – Other, live; DCAL - Dead coral with algae; CALG – Coralline algae; DCOR– Diseased coral; SAND – Sand, rubble, rock and boulder; UNKN – Unknown.)

Fig. 3 provides a summary of the hard coral data collected during this study. In Antigua the site selected for monitoring had the lowest percentage cover (4% and 3.8%) when compared to the other islands and also the lowest number of coral species (9 and 13). St Vincent on the other had the highest percentage cover (29.2%) and the highest number (29) of species.

Discussion

The coral reef monitoring programme was successfully implemented in seven countries in the Eastern Caribbean and plans are currently being formulated to conduct the second round of monitoring.

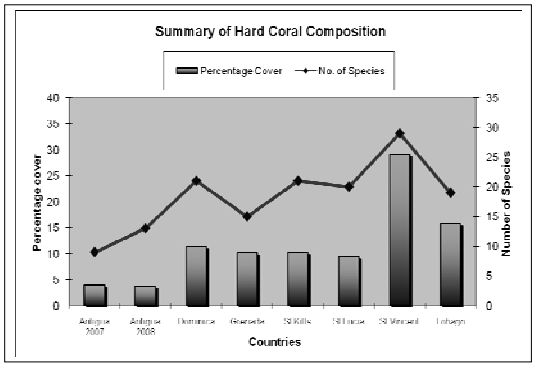

Figure 3: Graph summarising the hard coral composition (percentage cover and number of species) at the monitoring sites in Antigua, Dominica, Grenada, St Kitts, Saint Lucia, St Vincent and Tobago for the period September 2007 to April 2008.

The reefs in the Eastern Caribbean have been exposed to a variety of local (eg pollution and sedimentation from run offs) and regional (eg increase sea surface temperatures) threats, the impacts of which are different for each country. This monitoring programme provides the opportunity to establish a long term programme to assess changes in reef health over the long term. For some countries this monitoring programme would form the basis of the comprehensive reef health assessment while for others the data provided would support existing programmes.

In Antigua, although *Acropora palmata* beds were previously reported to be extensive at Little Bird Island in Antigua no colonies were observed during this assessment and the area appeared to have experienced significant disturbance which supports the observations of Bouchon et al (2004) particularly with respect to the low hard coral (4%) and high algal cover.

In the case of Dominica, it was felt that the 11.6% coral cover and the 21 hard coral species identified were not indicative of the full coral biodiversity within the SSMR (per com Fisheries Department Representative). Bouchon et al (2004) describe the reefs in Dominica as having "high hard and soft coral abundance, very low algal cover, no observable disease, no bleaching". The results from the four sites monitored did not reflect this therefore work is needed for a more accurate assessment of reef health in Dominica.

The Fisheries Department of Granada has proposed a system of marine protected areas for Grenada (Burke & Maidens, 2004) and it is expected that the results from this monitoring exercise will be used in conjunction with previously collected data to support this proposal.

Paradise Reefs, the monitoring site selected in St Kitts is located within the designated National Marine Park at Sandy Point and features giant basket sponges as part of the coral assemblage. Although this area is well used

by divers, its designation as a protected area prevents boats from anchoring and damaging the reefs.

The fringing reef communities along parts of the west coast of St Lucia are under pressure from tourism and coastal development (Burke and Maidens 2004). The SMMA has a comprehensive monitoring programme which provides data on a variety of coastal and marine parameters and the data collected from this monitoring exercise will be incorporated into their database.

For St Vincent & the Grenadines the monitoring site selected at Castle Bay had the highest coral cover and number of coral species despite its close proximity to the capital, Kingstown, and the impacts of runoff and discharges from the nearby rivers.

For Tobago it was felt that the results of the monitoring did not reflected the results of previous studies using photo quadrat surveys carried out in the area by Laydoo (1985) (per com IMA Representative). The main difference cited were the number of coral species found and the actual species identified. A more detailed evaluation of the studies, along with any other additional data that might be available, needs to be carried out before a conclusion can be drawn about these results.

There were a number of challenges faced in the implementation of this monitoring programme which have also served as a learning experience for all those participating in the effort. The most significant challenge was that of adequate numbers of personnel to carry out the preparatory work (site selection, marking of transects), monitoring and data analysis. This was partially overcome by having resources persons from the CMS leading the monitoring in each country and having the videotapes processed and analyzed by the CMS. More time was required for the training of the participants especially with respect to the data processing and analysis component to facilitate the carrying our of in-country analysis. There were also some logistical (e.g. boat availability, access to sites) and equipments problems (e.g. fogging and flooding of camera housings) and the issue of weather played a significant part in the delays experienced in completing the monitoring especially for Antigua.

Recommendations

These recommendations are based on the experience of this first monitoring exercise and should be considered for incorporation in the overall monitoring programme.

Representatives from the participating countries should together review and discuss the technical and logistical challenges of this programme with a view to refining the monitoring process. A review of the training should also be carried with the persons who participated in the training workshop to fine-tune and clarify the video monitoring protocol with specific emphasis on the data processing and analysis components. Training should also be provided to additional persons in the countries that request this, focusing on their specific areas of need. Proposed solutions should then be incorporated into the program for future monitoring.

Each country should review the site selected to ensure, based on the experience of the first monitoring exercise, that these sites are representative of the area being studied and are suitable for the long term monitoring programme. Once suitable sites have been decided on, permanent transects should be established where these have not been done to ensure that the same transects are monitoring over the long term. These sites should be geo-referenced.

There should be an increased focus on in-country coral species identification and data analysis particularly by the persons knowledgeable about the specific monitoring sites. This is presently carried out by the CMS, UWI in Jamaica. Each country should gather all other relevant data related to the site selected on anthropogenic issues such as pollution, over-fishing, sedimentation, turbidity and physical damage, which interact with climate factors and affect the status of the coral reefs.

Provision in the programme should be made carry out monitoring during coral bleaching invents to determine the extent of bleaching and the rate and nature of recovery. The CREWS network in the Caribbean provides the information which allows predictions of potential bleaching events. Closely associated to coral bleaching are the increase incidences of coral diseases which are now being linked indirectly to increased sea surface temperatures. Provision should also be made to include the monitoring of carol diseases if they occur. Where possible, other indicators used for assessing and monitoring coral reef status should be incorporated in the monitoring programme, such as but not limited to, coral recruitment, coral size distribution, fish species and abundance, abundance of herbivores and physical parameters.

Abstract. Sudan borders the western shore of the Red Sea, a sea recognised as being of global importance for marine biodiversity. A survey carried out during October / November 2007 provided the opportunity to assess the current status of the reefs, many of which have never previously been surveyed. Within the Sudanese Red Sea there is a pronounced biogeographical transition from reef communities that are characteristic of the northern Red Sea to those more representative of the southern Red Sea. Recreational and extractive use of resources is still moderately low however the condition of the reefs and the abundance of resources is highly variable. There are low abundances of several key families of commercial fin fish (particularly groupers and larger snappers) and invertebrate groups (particularly sea cucumbers and larger gastropod molluscs). There is also a conspicuous absence of sea urchins (*Diadema* spp. and *Echinometra* spp.) from many sites. The reefs of Sudan were impacted by previous coral bleaching events, although the extent of mortality was influenced by variability in community composition and local environmental conditions. The biogeographic trends within Sudanese waters and the variability in resource abundance and reef condition all have important implications for management planning.

Key words: Red Sea, sea urchins, coral bleaching

Introduction

The Sudanese Red Sea supports an extensive near-continuous fringing reef, a complex offshore barrier reef system, and numerous uninhabited islands. While some of the more accessible reefs, such as those in the vicinity of Port Sudan and Sanganeb Atoll, have previously been the subject of research (Head 1980, Merger & Schumacher 1985, Edwards & Head 1987, Reinicke et al. 2003), and others are renowned tourism dive sites (e.g. Sha'ab Rumi), many of the reefs have never previously been surveyed. More recent survey efforts focused on the establishment of two marine parks at Dungonab Bay and Mukawwar Island National Park (DBNP) (surveyed in 2002 and 2006) and Sanganeb Atoll Marine National Park (SMNP) (surveyed in 2006) (Fig. 1) improved the understanding about the current status of the reefal communities within these areas (Kemp et al. 2002, PERSGA/GEF 2004, APF 2006).

In 2007 a more geographically comprehensive habitat and biodiversity baseline survey was carried out on some of the un-surveyed reefs in the Sudanese Red Sea. The survey was part of the first phase of a larger programme which aims to link poverty alleviation and the protection of the environment of the Sudanese Red Sea through the implementation of Integrated Coastal Zone Management (ICZM). The ICZM programme, led by Equipe Cousteau, and is part funded by the European Commission in co-operation with a consortium of partners including the Higher Council for Environment and Natural Resources (HCENR) of the Red Sea State of Sudan, UNESCO, and PERSGA (The Regional Organization for the Conservation of the Environment of the Red Sea and Gulf of Aden). This paper presents the preliminary results from the baseline survey that will be used to assist the Government of Sudan to manage the anticipated developments in the coastal region.

Methods

During a four week boat based survey (October—November 2007) on board the MSY Elegante a survey team collected data on the habitats and biodiversity associated with coral reefs along the Sudanese Red Sea coast. The survey area spanned approximately 195 km of coast north to south, and extended approximately 75 km west to east, across 2° of Latitude (between 20°28'N and 18°45'N) and 1° Longitude (between 37°11'E and 38°10'E).

A combination of survey methods was adopted similar to those used elsewhere in the Red Sea and Gulf of Aden region to characterize and map the distribution and status of coastal and marine habitats and associated species assemblages. This paper considers the results of the detailed transect based surveys that were completed at 40 sites along the Sudanese coast. At each of these sites a team of surveyors completed a modified version of the Reef

Check survey protocol which included: (i) video transects to characterize the benthic cover (4 replicate 20 m transects); (ii) timed swims to record the diversity of hard coral species; (iii) belt transects to assess the abundance of key macro-invertebrates (4 replicate 20 m by 2m wide belt transects) and (iv) belt transects using an underwater visual census (UVC) method to record abundance estimates and / or species presence / absence data on indicator fish groups and fisheries groups (4 replicate 5 m belt transect counts, and timed swims). Data collected included: (i) Abundance of butterflyfishes and angelfishes (all individuals identified to species level), (ii) Abundance of groupers, snappers, emperors, parrotfish, (iii) Abundance of Napoleon wrasse and moray eels, and, (iv) Species richness of surgeonfish, triggerfish, damselfish, and wrasse.

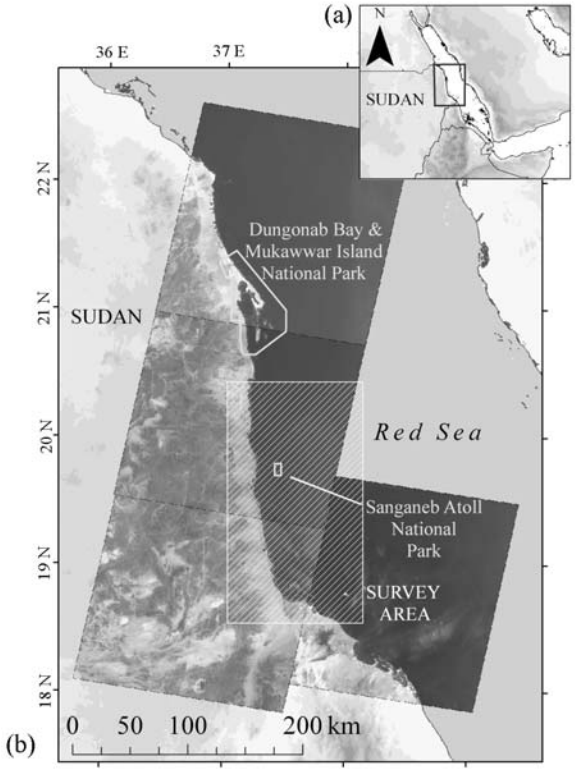

Figure 1: Map showing (a) the location of Sudan (Red Sea) and (b) The Sudanese Red Sea coast and the location of the existing marine protected areas at Dungonab Bay and Mukkawar Island National Park (DBNP) and Sanganeb Atoll Marine National Park (SMNP) and the 2007 survey area (hatched box).

Results

A total of 40 detailed transect sites were surveyed in 2007 and the key findings were as follows:

Benthos

Coral communities in the Sudanese Red Sea support more than 290 species, and transition between those communities characteristic of the northern/central Red Sea and those more typical of the southern Red Sea. Live hard coral cover on the fore reef slopes varied between 11% and 65% (Fig. 2a), and there were notable trends both north to south, and inshore to offshore, while more unusual high cover coral communities were found in sheltered shallow turbid areas. Reefs north of Port Sudan had a significantly lower cover of live stony corals, a higher abundance of both dead standing corals colonised by turfs or coralline algae, and rubble. The extensive mortality of corals on these reefs may of been due to a range of factors (e.g. coral bleaching, Crown-of-Thorns, *Drupella*), but is most likely due to coral bleaching during late 1998, as occurred on the around Dungonab (Kemp et al. 2002) and at similar latitudes on the reefs on the eastern Red Sea (DeVantier et al. 2000a, 2000b). By comparison, southern and offshore reefs supported higher live coral cover and healthy communities of bleaching susceptible species (e.g. *Acropora, Stylophora*), suggesting that these reefs may have avoided the major bleaching events of the past 10 years, most likely due to differences in the local environmental conditions.

Fishes

Pronounced north-south patterns in community structure were apparent, consistent with known patterns in Red Sea biogeography (Fig. 2b). Fish communities however also had very low abundances and diversity of lutjanids (snappers), lethrinids (emperors), serranids (groupers) and scarids (parrotfish) and other groups, which may be a result of overfishing, second-order coral mortality / bleaching effects, or a combination of both these factors (Fig. 2 c). Abundances of exploited species were particularly low in the Suakin archipelago.

Macroinvertebrates

Sea cucumber abundances were very low, suggesting that this group is heavily overfished. This is probably a recent development (within the past 6 to 8 years). Molluscs such as *Trochus* (*Tectis*), *Murex, Lambis* and *Strombus* were absent or present in very low abundance throughout the survey area, whereas *Tridacna* were common or abundant.

Sea urchins (*Diadema* spp. and *Echinometra* matthaei) were almost completely absent in the north and central parts of the survey area, and present only in very low densities in the southern area (Fig. 2 d).

Other Impacts and Threats

Coral diseases and sponge infestations were observed but these were not widespread, although incidents appear to have increased both within Sudan and the wider region in recent years (Klaus pers. obs.). Corallivores such as the Crown-of-Thorns starfish

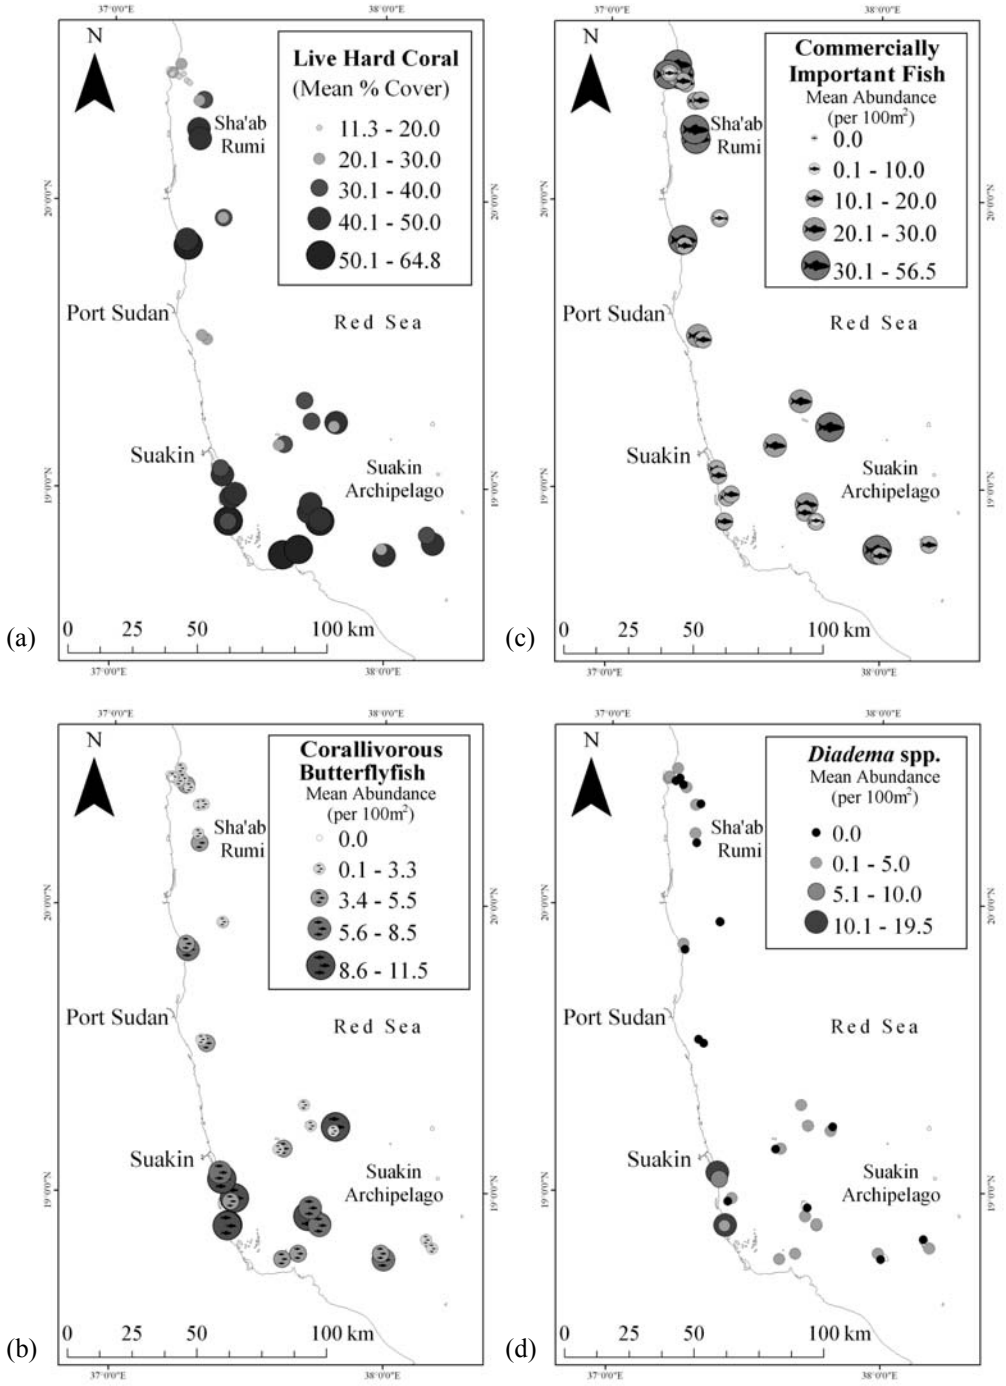

Figure 2: Maps showing some of the key findings from the 2007 survey (a) Mean percent live hard coral cover, (b) Mean abundance of corallivorous butterfly fishes (per 100m^2), (c) Mean abundance of commercially important fishes (per 100m^2) and (d) Mean density of *Diadema* spp. (per 100m^2)

(CoTs), *Acanthaster plancii* and *Drupella* spp. were found at most sites, numbers were generally low, and active outbreaks of CoTs were only found at two sites.

There were low abundances of commercially important fin fish (particularly groupers and large snappers) and invertebrates (sea cucumbers and gastropod molluscs).

Discussion

The composition of the benthic and fish communities found on Sudan's reefs reflects the influences of both the northern and southern Red Sea. Unusual, localized, 'geographically displaced' fish and coral communities may provide opportunities to understand the factors giving rise to biogeographic patterns in the region, and perhaps more widely (Kemp & Klaus, in prep).

The status of the coral communities on both the fringing and offshore coral reefs was highly variable, ranging from poor to good. Reefs to the north of Port Sudan had lower live coral cover and a higher abundance of both rubble and dead standing corals, colonised by turf and coralline algae, and the appearance characteristic of reefs that had been subject widespread coral bleaching event. Although there are few documented observations in the Red Sea during the severe 1997/1998 bleaching event that devastated large parts of the wider Indian Ocean, coral bleaching was observed on the reefs of northern Sudan at Dungonab (Kemp et al. 2002) and on Saudi Arabian reefs at similar latitudes in the eastern Red Sea in August-September 1998 (DeVantier et al. 2000a, 2000b). Corals on fringing and offshore reefs in the Dungonab area were observed to bleach in 1998, and the reefs were reported to be "*so bright white as to be visible from the shore",* while the weather conditions were "*calm and very hot*" (Andrea Bari [*of Dungonab Pearl Oyster Farm*], pers comm February 2002). The first systematic surveys in Sudan following the 1998 event were carried out along a 70 km section of coast in the Dungonab area to the north of Port Sudan in 2002 as part of the baseline surveys for the establishment of Dungonab Bay and Mukawwar Island Marine National Park (Kemp et al. 2002). By comparison, many reefs south of Port Sudan and offshore, showed little evidence of widespread impacts, still supported a high cover of live hard corals, including healthy communities of bleaching susceptible genera, suggesting that these reefs may have avoided exposure to the environmental conditions that caused coral bleaching and mortality on the reefs further north. The patterns in coral cover are reflected in the abundance of corallivorous butterfly fishes and other groups.

Other impacts included CoTs and *Drupella,* although these typically affected smaller patches of reef and their contribution to the spatial variability in the current status of Sudanese reefs was considered to be minor by comparison to the previous bleaching event. Minor outbreaks of CoTs have been recorded in Sudan since the 1970s, and they were present at low abundances throughout the areas surveyed (Kemp et al. 2002, PERSGA/GEF 2004, APF 2006, Cousteau 2007). The most severe outbreak observed during the three surveys undertaken between 2002 and 2007 extended across less than 200m of reef. The widespread coral mortality observed on the northern reefs was concentrated at depths of less than 10m, in contrast to coral mortality caused by CoTs outbreaks in, for example, Sinai, where outbreaks often begin at depths as great as 50m or more and, cause extensive coral mortality to similar depths (Salem 1999). *Drupella* was present at low densities throughout the survey area, and only observed at high densities in very specific habitats in Sudan (shallow areas of high density of *Stylophora* corals) (Kemp et al. 2002, 2003, APF 2006, Cousteau 2007).

Large snappers, groupers (*Epinephelus* spp. and *Plectropomus* spp.) and emperors (lethrinids) are taken by handline fisheries in Sudan. Their absence or very low abundance on most reefs suggests heavy fishing pressure. The low abundance and diversity of parrot fish is less easily explained since they are not targeted in local fisheries. Possible causes may be their dependence on healthy coral reef habitats and lag effects of coral bleaching on fishes (Graham et al. 2007).

The extremely low abundance of many commercially important species of holothurians, and the absence or low abundance of some exploited gastropods suggests that overfishing of these macro-invertebrate groups is widespread.

The complete absence of the common sea urchins (*Echinometra* spp. and *Diadema* spp.) from many reefs is a cause for concern, which reflects the trends recorded by the Reef Check programme (Hodgson and Liebeler 2002), where significant falls in abundance of *Diadema* were recorded on coral reefs of the Indo-Pacific, including the Red Sea, between 1998 and 2001. Historical data on distribution and density of sea urchins in the Red Sea, especially of the important species *Diadema setosum*, is limited, but abundances may be naturally low on some of the offshore deep water reefs. The absence of *D. setosum* from Sanganeb was repeatedly noted by Schuhmacher (1974, 1989) and Kroll, in Schuhmacher *et al. (*1995). The same authors did however note that *Diadema* "is abundant in the northern Red Sea, where it plays a major role in controlling reef development". Reef tops without urchins were, uncharacteristically for the Red Sea, overgrown with small macroalgae, a possible consequence of reduced grazing from both parrot fish and sea urchins. There is no immediately obvious reason for the absence of sea urchins as they were still common in some areas, primarily sheltered, relatively turbid inshore locations such as the large lagoon at Sha'ab Shubuk. These findings require further investigation.

The Future

Until recently, the Sudanese coast has remained

relatively unaffected by the coastal development activities taking place in other countries of the Red Sea. Anthropogenic influences are still mainly limited to a 70 km strip extending from Port Sudan to Suakin, where there are two major ports, oil refineries, a desalination plant, saltworks, power station, a shrimp farm and the new Red Sea Economy Free Trade Zone (although increased development has also recently begun to spread northwards from Port Sudan). The damage to coastal habitats due to construction within this strip is already extensive, and major industrial facilities have been sited with little or no regard to their potential negative environmental impact. Following the peace agreement which brought the war in the south of Sudan to an end, and the recent discovery of oil and gas reserves, rapid coastal development is likely to cause unprecedented economic transformation that will result in a surge in coastal development and associated risks.

Most of the coastal and offshore reef complexes are still relatively undisturbed by human pressures other than fishing. There is a small dive tourism industry, composed of between 8 and 10 boats operating out of Port Sudan and from Egypt. Further rapid development of tourism and other sectors is anticipated as more investors are attracted to Sudan. The increasing development will make the Sudanese coastline more attractive and accessible to the wider foreign and local public. The new coast road from Port Sudan to Egypt is nearing completion, making huge areas of previously relatively undisturbed coast easily accessible, and creating the opportunity for development to the north of Port Sudan but with all the associated risks to coastal habitats.

The focus of future development is likely to continue to be between Port Sudan and Suakin, and the coast between Port Sudan and the Dungonab Bay MPA. The results of this survey suggest that the reefs of Sudan are already suffering from overfishing and coral bleaching mortality, among other impacts. It is therefore of paramount importance that Sudan's designated Marine Protected Areas are given high priority, and that fisheries management plans be implemented. The need for effective planning, and a strategic approach which incorporates considerations of environmental sustainability, is urgent.

Conclusions

Sudan's 750 km long coastline and numerous uninhabited islands and offshore reefs are within the centre of marine diversity in the Red Sea. The country has two MPAs with great potential for UNESCO World Heritage status. Developments in and around Port Sudan are expanding, and the port in this city provides the only maritime access to a country that is otherwise land-locked. The ICZM Programme is uniquely situated to help mitigate future conflicts that may arise over natural resource use, distribution and over-exploitation. This survey is partly responding to the urgent need to provide decision makers with the tools and information necessary to manage the predicted development of the coastal area, whilst protecting its natural heritage.

The Jamaica Coral Reef Monitoring Network (JCRMN)

M. Creary[1]

1) Centre for Marine Sciences, University of the West Indies, Kingston 7, Jamaica

Abstract. The Jamaica Coral Reef Monitoring Network (JCRMN) was launched in June of 2003 by several organizations involved in coral reef monitoring, research and management. The objectives of the JCRMN were to gather information about the coral reefs, stimulate interest in the monitoring of the Jamaican coral reefs, train persons in coral reef monitoring methodologies and to develop a sustainable coral reef monitoring programme. Since its inception monitoring was carried out in the Portland Bight Protected Area, Negril Marine Park, Discovery Bay, Portland, the Port Royal Cays and many other sites around the island. In addition, divers from member ENGOs, hotel resorts and scuba diving clubs, have been trained in the Reef Check Method of coral reef monitoring. The JCRMN has also participated in training and monitoring in Haiti and the Turks and Caicos Islands. Despite the success of the network the development of a sustainable monitoring programme based on external funding and volunteer divers remains the biggest challenge facing the JCRMN. The JCRMN is coordinated through the Caribbean Coastal Data Centre (CCDC) of the Centre for Marine Sciences at the University of the West Indies, Jamaica.

Key words: Coral reef monitoring, Jamaica, JCRMN, GCRMN

Introduction

Jamaica is the third largest island in the Caribbean, after Cuba and Hispaniola, and is comprised of a highland interior with peaks an plateaus running the length of the island surrounded by relatively flat coastal plains (Fig.1). Fringing reefs occur on the narrow 1-2km shelf along most of the north coast and grow sporadically on the much broader shelf (approximately 20km) of the south coast. In addition, reefs and corals are found on neighbouring banks of Pedro Cay and Morant Cay to the south and south west of the island (Burke and Maidens 2004).

Figure 1: Map of Jamaica with insert showing its position in the Caribbean Sea.

The reefs of Jamaica have suffered significant decline since the 1970's. The physical impacts of hurricanes and coral disease combined with the die-off of the grazing sea urchin Diadema in 1983 marked the decline of the Jamaican coral reef. Recovery has been difficult because of the added impacts of human activities which have led to over-fishing, sedimentation caused by soil erosion, nutrient pollution and poorly planned coastal development (Woodley 1992; Hughes 1994). These conditions have been further exacerbated by the ravages of subsequent hurricanes and the effects of coral bleaching.

Rationale for the formation of the JCRMN

The Jamaica Coral Reef Monitoring Network (JCRMN) was launched in 2003 by a number of agencies, institutions and organizations involved in coral reef monitoring, research and/or management (Table 1). The objectives were to develop a vibrant coral reef monitoring network for Jamaica and to provide relevant data and information on the status of Jamaican coral reefs and related ecosystems to inform decision-making at different levels. The formation of the JCRMN was motivated by the existence of the Global Coral Reef Monitoring Network (GCRMN), a network that is involved in coral reef monitoring in 80 countries around the world. The GCRMN functions through a number of independent nodes in various regions of the world. Jamaica is the Coordinator of the Northern Caribbean and Atlantic Node of the GCRMN which also includes The Bahamas, Bermuda, Cayman, Cuba, Dominican Republic, Haiti and the Turks and Caicos Islands.

The Caribbean Coastal Data Centre (CCDC), as the coordinator of the Node, aims to increase the level of collaboration among institutions and countries involved in monitoring within the Node and to assist in improving regional capacity for assessing reef health in the long term and providing appropriate management solutions.

- The Institute of Jamaica
- Mainstreaming Adaptation to Climate Change

Coral Reef Monitoring Methodology

The Reef Check methodology was selected because it is the world's largest volunteer coral reef monitoring programme and provides basic data on the health of coral reefs. Reef Check focuses on the abundance of particular coral reef organisms that best reflect the condition of the ecosystem and that are easily recognizable by non-specialists. The training manuals and field guides are available on their website (www.reefcheck.org) where they also provide technical support (on survey methodology, equipment, data recording, data submission and data analysis) to its registered members. The advantages of the Reef Check method are that it is simple, rapid and inexpensive. This methodology employs low-tech techniques, which facilitates the combination of the manpower of volunteers with the expertise of scientists (Hodgson et al.. 2003). This simple but scientifically robust sampling method has provided data on the condition of reef environments throughout the world and has been adopted as the standard monitoring protocol by marine park managers, national governments, scientific institutions as well as many volunteer teams.

Training and Monitoring

Since the inception of the JCRMN in 2003 approximately 90 persons from various locations around the island, including persons from Haiti and the Turks and Caicos Islands have been trained in the Reef Check Monitoring methodology and have participating in monitoring. Coral reef data has been collected from at least 53 coral reef sites in Jamaica, five sites in Haiti and 18 sites in the Turks and Caicos Islands. Particularly with respect to Jamaica, attempts have been made to monitor the site annually and this has been accomplished at Negril (2001-2006) and Drunkenmans Cay (2003-2007) in Port Royal. The JCRMN was also been able to purchase some equipment and materials to facilitate regular monitoring.

As a result of the activities of the JCRMN the University of the West Indies (UWI) has included the Reef Check methodology in its credited scuba diving course. This association between the UWI and JCRMN provides the opportunity for newly trained divers to participate in a programme that is contributing to the management of the marine environment while allowing them to improve their diving skills.

There is also now an active *egroup* which provides updates and is used to coordinate the volunteers. Regular meeting of the JCRMN are held to evaluate the progress of the network, plan for future activities and explore funding opportunities. The data collected is archived at the CCDC and also sent to Reef Check International. The data is used to prepare reports for the CCDC and other members of the network (e.g. Linton 2003a and 2003b; Linton et al. 2003; Jones 2006, NEPA 2008) and also used in contributions to the *Status of the Coral Reefs of the World* reports (Jones et al. 2004, Creary et al. in press) and the "*Status of Caribbean Reefs after Bleaching and Hurricanes in 2005*" (Jones et al. 2008) publication produced by the GCRMN,. The achievements of the JCRMN have also been the subject of newsletters, workshops and conference presentations.

Funding

Funding has been provided by ICRAN Project of the UNEP-CEP and the British High Commission (in Jamaica) to conduct the training and monitoring exercises in a number of sites in Jamaica and in Haiti. For the training exercises that took place in Negril and Boscobel accommodation were provided by Sandals International, Beaches Resorts and other hotels in the area. DEFRA (Department for Environment, Food and Rural Affairs, UK) provided the funding to monitor the coral reefs within the Portland Bight Protected Area and has also made funds available to carry out additional training and monitoring as well as the hosting of a stakeholders workshop (Creary and Jones 2007) to

report on the work of the JCRMN. In kind support is provided by the participating individual and agencies of the JCRMN.

Selected Results of the JCRMN Monitoring Programme

Jamaica

The Portland Bright Protected Area (PBPA), the largest protected area in Jamaica (1,876 km^2) is located on the south coast of Jamaica and is currently managed by the Caribbean Coastal Area Management Foundation (CCAM) a members of the JCRMN. The marine area (approximately 70% of the PBPA) has widespread coral reefs associated with the 16 cays and several shoals (Linton et al.. 2003). Extensive surveys were conducted by the JCRMN in conjunction with CCAM during 2004 and 2005 at nine sites associated with the cays and shoals. The results from these assessments shows variable hard coral cover ranging form 0% to 34% with a mean of 20% (Fig. 2). Between 8 and 13 coral species were identified and the most common species were those of *Porities spp* and *Montastrea spp*. At the site with no hard coral present the substrate was dominated (48%) by algae. Sea urchin densities were generally low but parrotfish were abundant at most sites (Jones 2006).

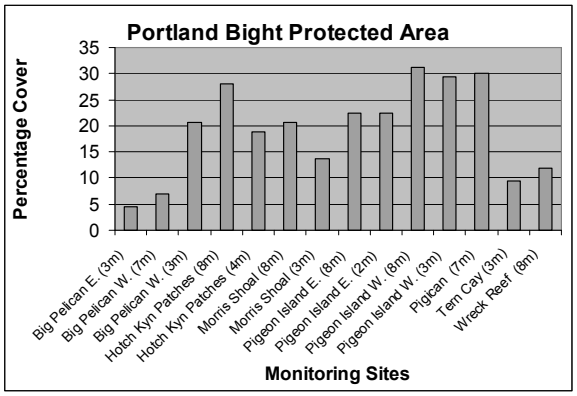

Figure 2: Hard coral cover at sites within the Portland Bight Protect Area, Jamaica.

Four sites located within the boundaries of the Negril Marine Park have been monitored annually since 2001. The sites (Ireland Pen, Bloody Bay, El Punto Negrilo and Little Bay) are all exposed and experience varying levels of fishing pressure and anthropogenic impact (Linton 2003a). Fig. 3 provides the most recent results (2006) of the assessments carried out at shallow and deep locations at the sites in Negril. Coral cover was low ranging from 6.3 to 18.1% with an overall mean of 11.5%. At all sites with the exception of Bloody Bay the deeper sites had higher coral cover.

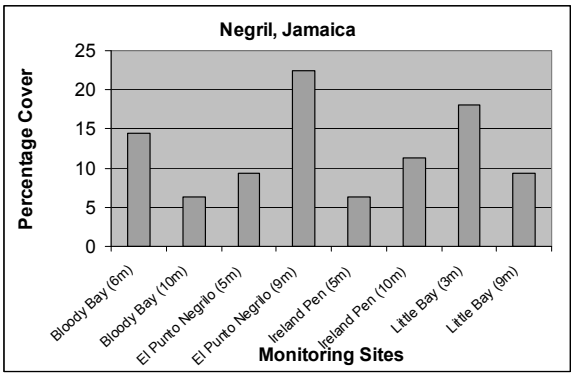

Figure 3: Hard coral cover at four sites in the Negril Marine Park, Jamaica

Haiti

A team led by the JCRMN visited Haiti during the period September 15-20, 2003 to assist the Foundation pour la Protection de la Biodiversite Marine (FoProBIM), a Non-Governmental environmental organization with the assessment of reef sites at Les Arcadins. A two-member team from Haiti was trained during this period. Surveys were conducted at 5 sites at two depths. The sites were: Trou Forban, Ti' Teal, Ilé Fa, Ilé Sud and Bo wout Montrouis.

Visual surveys of the sites revealed generally healthy reefs. They appear to be in reasonably good condition, with the exception of some sites that had relatively high percentage of nutrient indicating algae, suggesting some anthropogenic impacts. Preliminary data analyses indicated a range of coral cover from a high of approximately 50.0% to a low of 7.0% (Fig. 4); cover by Nutrient Indicating Algae (NIA) was also relatively low. Fish populations were low at all sites ranging from 0.5 to 5.0/ 100 m^2 (Linton 2003b).

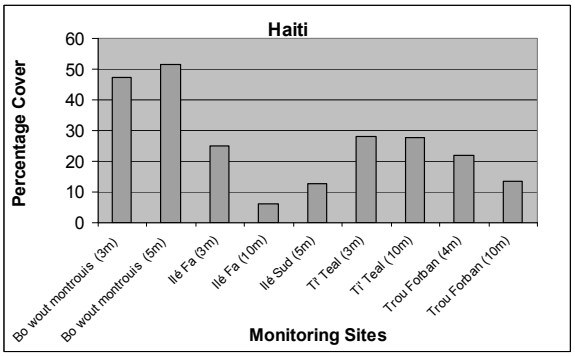

Figure 4: Hard coral cover at five sites assessed in Les Arcadins, Haiti.

Turks and Caicos Islands

During August 3-19, 2007, the Department of Environment and Coastal Resources of the Turks and Caicos Islands, along with members of the

JCRMN completed a wide scale survey and assessment of 18 sites around the major islands to establish the current state of the coral reef resources. These results showed that live coral cover on hard bottom averaged about 16% with a range of 6.3–38.8% (Fig. 5).

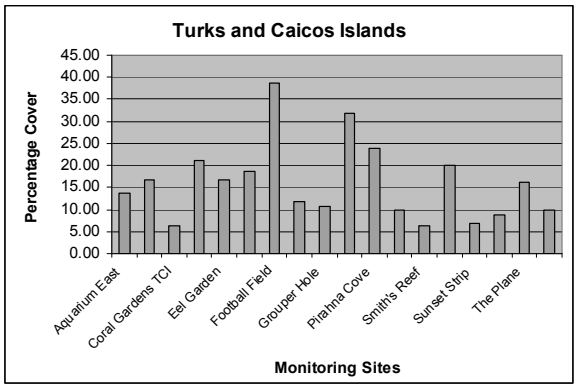

Figure 5: Hard Coral Cover for 18 sites in the Turks and Caicos Islands.

Challenges faced by the JCRMN

Despite the successes there have been challenges faced by the JCRMN in the implementation of a comprehensive monitoring network in Jamaica.

The logistics of organizing volunteers can often be problematic. As most of the work has to be done on the weekends monitoring is limited to two or three days at the most. If monitoring is to be carried out during the week volunteers need to request time off from work. Even those who work in the environmental field have to find time in their work schedule to participate in the JCRMN activities, separate and apart from their regular work schedule. Volunteers also use their own equipment and the maintenance and replacement of these is not factored into the monitoring programme.

The varying diving and species/substrate identification skills of the divers also have to be taken into consideration. Often times the more skilled divers carry out the majority of the monitoring and are sometimes called on to finish up the data collection initially undertaken by the less-skilled divers. It has also been observed that for those divers who are not scientists, their interest in doing "work" dives wanes after a number of monitoring exercises because the monitoring does requires focus and concentration to complete the task within a specified time (before the divers becomes exhausted or air gets too low).

Funding is needed to ensure the continuity of the monitoring programme. Although the volunteers are not paid, funds are required to purchase monitoring equipment and supplies and to cover the cost of transportation, accommodation and meals. In-kind contributions are helpful but tend not to be sustainable. In addition to coordinating the activities of the JCRMN data processing and report preparation is presently carried out by the CCDC, which is presently understaffed.

The Future of the JCRMN

The JCRMN has established a schedule of monitoring primarily focused on the annual assessment of existing sites giving priority to the marine protected areas. Provision has also been made to add new sites for which no information exists. Reef Check training for recently trained divers (those trained through USAC and UWI) who are interested in becoming JCRMN volunteers and also for members of the other interested agencies will continue.

In the longer term efforts are being made to obtain funds to support the permanent position of JCRMN Coordinator whose responsibilities would be to develop the interest of the group and to coordinate activities geared towards establishing and implementing the framework for coral reef monitoring in Jamaica. Additional funding would also be required to continue training and monitoring and to support the establishment of additional monitoring networks in the other islands of the Northern Caribbean and Atlantic Node of the GCRMN.

Conclusion

The Jamaica Coral Reef Monitoring Network through a cadre of trained volunteer divers has managed to reduce the costs associated with coral reef monitoring. Although there are challenges regarding manpower and funding the members of the network are committed to facilitating its long-term sustainability.

Acknowledgment

The JCRMN could not have achieved the success that it has with out the contribution of the member organizations and volunteer divers. **Jamaica -** Noylis Amair, Brooke Anderson, Kerrith Armstrong, Richard Baddal, Devon Brown, Damany Calder, Channeil Cadogan, Ansurd Carey, Michael Clarke, Wayne Clarke, Norman Clayton, John Cleland, Tameka Clough, Donald Comer, Monique Curtis, Lauren DeFino, Krishna Desai, Edward Downer, Rachel D'Silva, Raymond Earle, Lyle Edwards, Peter Edwards, Tracey Edwards, Anthony England, Nadia-deen Ferguson, Iona Flett, Sheena Francis, Peter Gayle, Linvel Getten, Elfred Greenfield, Mark Gold, Marlon Goldson, Sean Green, Dave Guiness, Kapleton Hall, Tamia Harker, Brandon Hay, Avril Hazlewood, Ainsley Henry, Marlon Hibbert, Nicholas Jack, Kimberly John, Loureene Jones, Ivanna Kenny, Matthew Lee, Jahsen Levy, Dulcie Linton, Michael Loftin, Kristoffer Lue, Suresh Martin, Elizabeth McGhie, Michelle McNaught, Judith Mendes, Malden Miller, Bryan Murray, Tadaomi Nakai, Minke Newman, Jenny Pearce, Shanti Persaud, Andre Pitter, Clayton Powell, Norman Quinn, Marsha Robinson, Dana Roeber, Andrew Ross, Chalene Roye, Daniel Scarlett,

Coral Bleaching Mortality and Resilience at Stetson Bank, a High Latitude Coral Community in the Gulf of Mexico

JL DeBose, GP Schmahl, MF Nuttall, EL Hickerson

NOAA/Flower Garden Banks National Marine Sanctuary, Galveston, TX 77551

Abstract. Stetson Bank, located near 28.2° N, 94.3° W in the northwestern Gulf of Mexico, approximately 110 kilometers offshore of Galveston, Texas, is an uplifted claystone feature associated with an underlying salt dome. Due to the influence of the warm, clear waters of the Gulf Stream Loop Current, Stetson Bank supports a well-developed benthic community comprised of tropical marine sponges, coral and other invertebrates. Living coral cover, predominately *Millepora alcicornis*, can comprise up to 30% of the reef surface. A long-term monitoring program was initiated in 1993 consisting of 66 permanently marked stations on the reef surface that are photographed annually and analyzed for changes in community structure and benthic cover. In the summer of 2005, significant mortality of coral was documented in association with a major bleaching event in the Gulf of Mexico. In addition, the area was subject to significant coastal runoff resulting from two major hurricanes (Katrina and Rita). The synergistic effect of both coastal runoff and elevated temperature may have contributed to mortality in 2005. Here we present an analysis of monitoring data from 2004-2008 and evidence of possible resiliency of the coral-sponge community of Stetson Bank.

Key Words: coral bleaching, resiliency, Gulf of Mexico, Millepora, Stetson Bank

Introduction

Stetson Bank is one of a number of topographic features associated with underlying salt domes located in the northwestern Gulf of Mexico (Fig. 1; Rezak et al. 1985). Rising from surrounding water depths of over 55 meters, Stetson Bank crests to within 15 to 25 meters of the sea surface. The main feature of Stetson Bank is made up of uplifted claystone and siltstone pinnacle formations that harbor a well developed coral-sponge community. Stetson was first described in the 1950's (Carsey 1950; Stetson 1953; Neumann 1958) due to increasing interest of the oil and gas industry in offshore oil exploration along the continental shelf.

The clay/siltstone pinnacle structures of Stetson Bank support a unique coral and sponge community. Surrounded by a clay-mud bottom, the pinnacles rise to within 15 meters of the water's surface, providing structure above the turbid depths into the relatively clear, warm surface waters. The predominant benthic species on Stetson Bank is the hydrozoan *Millepora alcicornis* (fire coral) accounting for up to 30% of the reef surface in the pinnacle area. In addition, eleven other species of hermatypic corals have been documented, including *Diploria strigosa*, *Stephanocoenia intersepta*, *Madracis mirabilis*, *Madracis decactis*, and *Agaricia fragilis*. Sponges, primarily *Chondrilla nucula*, *Ircinia strobilina* and *Agelas clathrodes*, comprise up to another 30% of the benthic cover. A running total of 180 species of fish, including several species of sharks and rays (Pattengill 1998), 644 species of invertebrates, including mollusks and echinoderms, and 2 species of turtle (*Caretta caretta* and *Eretmochelys imbricata*) also inhabit this coral-sponge community (see http://www.flowergarden.noaa.gov/ document_library /science/recdivingspecieslist.pdf).

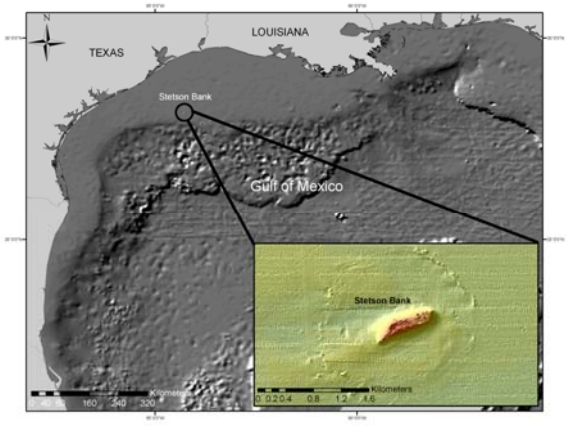

Figure 1: Location of Stetson Bank in the northwestern Gulf of Mexico. Inset shows bathymetry of Stetson Bank and surrounding deeper ring of siltstone pinnacles. Bathymetry provided by USGS/Gardner.

In 1996, Stetson Bank was incorporated into the Flower Garden Banks National Marine Sanctuary under revisions to the Marine Protection, Research

and Sanctuaries Act of 1972 (now the Marine Sanctuaries Act). Since 1993, a long-term monitoring program has been in place, utilizing permanent photographic stations, fish counts and random transects, as well as temperature and salinity probes. Initially, 66 long-term photographic stations were established, of which 44 station locations are currently known. Long-term monitoring cruises occur every summer, in June or July, weather permitting.

In 2005, a Caribbean wide bleaching event (for more information, see http://coralreefwatch.noaa.gov /caribbean2005/) severely impacted Stetson Bank, coupled with two hurricanes (Katrina and Rita) which caused mechanical damage as well as an increase in coastal runoff. A dark plume from the Mississippi River and coastal Louisiana encircled the banks for a few weeks after Hurricane Rita passed (Fig. 2). Here we present an investigation into the amount of change and degree of resiliency of Stetson Bank after this widespread bleaching event and repeated impacts from two hurricanes, through an analysis of five years of monitoring data, from June 2004 to June 2008.

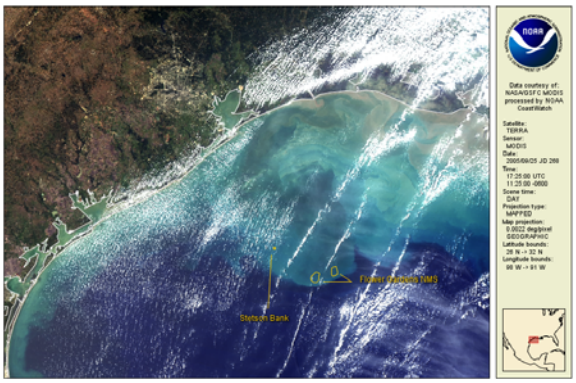

Figure 2: Satellite imagery showing the plume of coastal runoff elicited by Hurricanes Katrina and Rita. The plume moved over 100 miles south into the Gulf of Mexico, directly over Stetson and the Flower Garden Banks. This image is dated 25 September 2005, one day after Hurricane Rita's landfall. Data is courtesy of NASA/FSFC MODIS, processed by NOAA Coast Watch.

Material and Methods

Long-term monitoring cruises were conducted during the weeks of June 14 – 16, 2004, June 13 – 15, 2005, June 19 – 21, 2006, July 22 – 25, 2007, and June 16 – 18, 2008. From 2004 through 2007, a total of 51 different stations were photographed with a Nikonos V camera, with a 15mm lens, and two Ikelite 200 underwater strobes, mounted on a 1 meter T-frame with a bubble-leveler and compass. 100 ASA Fujichrome Sensia II film was used. The Nikonos was focused to 2.6 feet, f 8, on auto-exposure. The area of coverage was 1.6 m^2. Slides were commercially developed and scanned at 1200 pixels per inch (Nikon LS1000). In 2008, a Nikon Coolpix P5000 digital camera, housed in an Ikelite underwater housing, with two Ikelite DS125 sub-strobes and an Ikelite wide angle lens adapter, replaced the Nikonos V film camera. The digital camera was mounted on a modified T-frame (1.25 m in length), which provided a slightly larger coverage area than the Nikonos V. After digital images were downloaded, image distortion was removed using Photoshop CS2 software (V9.0.2, Adobe Systems Inc.), and then the image was cropped to maintain 1.6 m^2 coverage, the coverage obtained by the Nikonos V. Benthic cover was determined from a random overlay of 30 points using Coral Point Count with Excel extensions software (CPCe V3.5; National Coral Reef Institute (NCRI), Florida; Kohler and Gill 2006).

Sea surface temperature data were obtained from a National Data Buoy Center (NDBC) 3-meter discus buoy (Station 42019, 27.91˚ N, 95.36˚ W), located 60 nautical miles south of Freeport, Texas and 58 nautical miles west-southwest of Stetson Bank. The NDBC buoy reads the water temperature at 0.6 m below the water surface and is positioned over a water depth of 82.3 m. Bottom temperatures were obtained from HOBO temperature loggers (HOBO Water Temp Pro [H20-001]) and data sondes (YSI 6600 Series) placed on the crest of Stetson Bank at 23.5 m depth.

Statistical analysis

Percent cover values for major species categories (i.e., Coral, Sponge, Algae, Coralline Algae, and Other) could not be transformed to conform to a normal distribution. Therefore, percent cover data for each major species category were analyzed using non-parametric Friedman's ANOVA. Photographic stations which were not consistently photographed for all five years were not included, which left 39 out of 51 stations for the analysis. All tests were performed using Statistica software (6.0; StatSoft, Inc.).

Results

Changes in percent benthic cover

Percent coral cover changed significantly between 2004 and 2008 (Friedman's ANOVA; $\chi_{37,4} = 85.63$, $P < 0.001$), decreasing dramatically after 2005 (Table 1). Specifically, *Millepora alcicornis* decreased by 80% from 2005 levels and has not recovered as of 2008 (Fig. 3). Other hermatypic coral species have shown minor fluctuations in percent cover from 2004-2008, but were generally stable (3.5% in 2005; 4.2% in 2008).

Algal cover also changed significantly over the five years ($\chi_{37,4} = 82.93$, $P < 0.001$). In general, algal cover increased since 2005, from 29% to a peak of 63% in 2007, but decreased to near 2004 levels at 49% in 2008. Specifically, percent cover of *Dictyota*

fell from a high of 26% in 2006 to 3% in 2008, while turf-algae matrix increased to a high of 36% in 2007, and then decreased to 5% in 2008. Coralline algae (Corallinaceae) increased from 2% in 2004 to almost 9% in 2008 ($\chi_{37,4} = 29.58$, $P < 0.001$).

Sponge cover also changed significantly over time ($\chi_{37,4} = 19.72$, $P < 0.001$), decreasing from 27% in 2005 to a low of 18% in 2007. However, in 2008, overall sponge cover increased to 23%. Sponge species showed differing trends in cover. *Chondrilla nucula* decreased from 5% in 2005 to 0.2% cover in 2008. In contrast, *Ircinia strobilina* remained between 8-10% cover, and *Agelas clathrodes* between 1-2% cover between 2004 and 2008.

'Other' percent cover, which includes bare substrate, substrate rubble and mobile organisms, also changed significantly over time ($\chi_{37,4} = 15.74$, $P = 0.003$), decreasing from 10% to 6% in 2006, and then increasing to 12% in 2008.

Table 1: Percent benthic cover, averaged over all photostations, (± standard error, s.e.m.) from 2004 through 2008. The bleaching event occurred during the summer of 2005. Category 'other' in the table represents urchins, fish and other organisms which appeared under the random point generated by CPCe software.

Changes in temperature and salinity regime

Sea surface temperatures reached a peak in 2005, with water temperatures spiking to 30°C or greater on 67 days of the year (Table 2). Winter temperatures were also considerably milder than other years, with only 27 days falling below 20°C. In comparison, 2006 reached similar high, as well as low, sea surface temperatures, though for not as many days as in 2005.

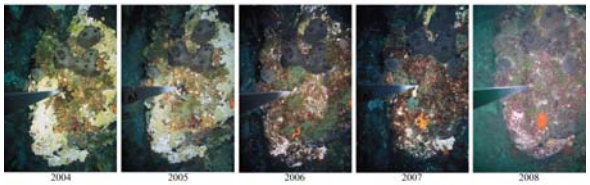

Figure 3: An example from one long-term photostation from 2004 to 2008. An obvious shift from *Millepora* to algae and sponge-dominated substrate is apparent in this series of photographs. In 2004 and 2005, *Millepora* (yellow coloration) is shown in relative abundance on the pinnacle, but is overgrown by algae in 2006 and 2007.

Sea surface and HOBO temperatures showed seasonal fluctuations over the mid-shelf area and Stetson Bank, respectively (Fig. 4 A, B). HOBO probes reported lower temperatures on the crest of Stetson than nearby, mid-shelf sea surface temperatures obtained from the NDBC surface buoy (e.g., August 7, 2005; Fig. 4A: 31.29°C SST; Fig. 4B: 29.26°C HOBO). Further, there were several sudden drops in temperature evidenced by the HOBO dataset, which were not reflected in the SST dataset (e.g., July 15, 2005: 29.8°C SST, 24.6°C HOBO). These discrepancies could be explained by the occurrence of cold water thermoclines over Stetson Bank during the summer months.

Year	Number of days SST reached 30 C	Number of days SST fell below 20 C	Mean temperature (± s.e.)	HIGH	LOW
2004	34	63	24.980 ± 0.044	31.6	15.2
2005	67	27	25.157 ± 0.040	33.1	18.8
2006	40	19	25.036 ± 0.037	33.1	18.8
2007	27	59	24.881 ± 0.039	31.8	18
2008*	7	48	22.977 ± 0.049	31.9	18.3

Table 2: Temperature records from Stetson Bank from 2004-2008. Asterisk denotes temperature data was not calculated from a full year; data is shown up to June 30, 2008.

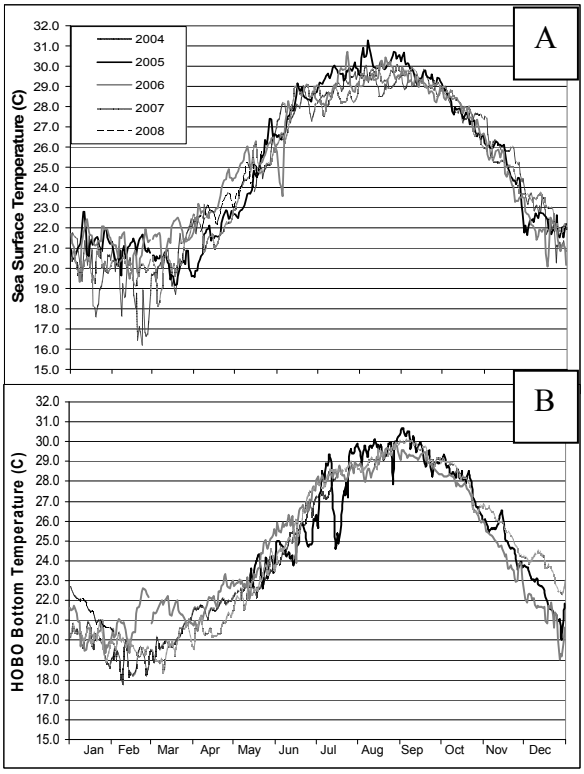

Figure 4: Average daily temperatures from 2004 – 2008. (A) Sea surface temperatures from NDBC Buoy 42019. (B) Bottom temperatures from the surface of Stetson Bank (23.5 m depth) from HOBO temperature probes.

Salinity was not measured as consistently as temperature due to instrument difficulties. However, a particular salinity regime emerged from the datasonde measurements. There were repeated freshwater influxes to Stetson Bank between 2004 and 2008

(data not shown). However, freshwater influxes in 2005 seemed to be of greater duration and extent than in the other years of this study. To contrast the extent of the lower salinity regime in 2005, in 2006 the average yearly salinity was 35.3 ppt, compared to 32.9 ppt in 2005. Throughout the end of July and August of 2005, daily average salinity measurements were as low as 27 ppt, and with the passage of Hurricane Rita, salinity again decreased from an average in September of 35 ppt to an average daily low of 32 ppt on October 2 (see Fig. 5).

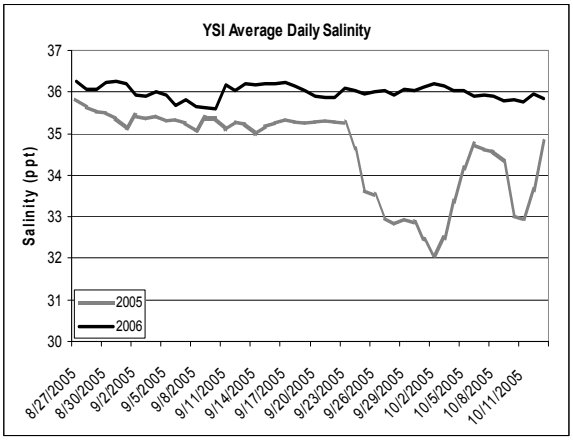

Figure 5: Average daily salinity measured between August and October, 2005 and 2006. Salinity was measured with a datasonde/YSI on the surface of Stetson Bank (23.5 m depth). Hurricane Katrina passed through the Gulf of Mexico on August 28, 2005; while Hurricane Rita passed through the Gulf on September 23, 2005.

Discussion

Though previous studies have suggested that the benthic community of Stetson Bank is relatively stable (Bernhardt 2000), this study is the first to report a dramatic change in percent cover of Stetson Bank's benthic community. This analysis allows for investigation into questions regarding the mechanisms of recovery or resiliency of this high-latitude coral-sponge community.

Several trends in percent cover are apparent from the analysis of the five years surrounding the bleaching event of 2005. Prior to the Caribbean wide bleaching event in 2005, Stetson Bank supported 27% coral cover. After 2005, overall coral cover fell to 7%, with *Millepora* suffering the largest decrease and not recovering as of the 2008 monitoring effort. The other hermatypic coral species of Stetson Bank (e.g., *Diploria strigosa, Stephanocoenia intersepta, Madracis decactis, Madracis mirabilis*, and *Siderastrea radians*) appeared stable, remaining at around 4% of the benthic cover throughout 2004 to 2008. This demonstrates the significant differential response of *Millepora* to bleaching compared with other species of hermatypic coral. The composition of sponge species varied between 18-27% throughout the five years. However, there was a dramatic decrease in *Chondrilla nucula* percent cover after 2005. Bleaching in sponges is not well documented (see Vicente 1990; Fromont and Garson 1999) and though we can not say from this dataset that the mortality of *C. nucula* was due to bleaching, *C. nucula* virtually disappeared between the 2005 and 2006 monitoring cruises. Further, the disappearance of *C. nucula* at Stetson Bank is an opposite response from the increase in *C. nucula* cover reported from the reefs of Belize after the 1998 coral bleaching episode (Aronson et al. 2006). Along with the varied success of the sponge species, there was an initial increase and subsequent decrease in algal cover. Concomitant with this decrease in filamentous and macro-algae, coralline algae and turf-algae matrix has steadily increased since 2005.

Although the benthic community has not recovered to pre-2005 levels, trends observed in this study suggest possible signs of resiliency of the reef ecosystem of Stetson Bank. An increase in coralline algae, relatively stable hermatypic coral and sponge cover and decreasing macroalgal cover (after an initial spike) have been cited as possible signs of reef resiliency elsewhere (see Birrell et al. 2005; Smith et al. 2008). However, understanding the details of the disappearance of both *Millepora alcicornis* and *Chondrilla nucula* and the interaction of the overall biological community with trends in temperature and salinity regimes is equally important in determining the overall resiliency of Stetson's *Millepora*-dominated community.

The temperature data from Stetson Bank demonstrate differences in accuracy between the sea surface (SST) and bottom (HOBO) temperature measurements. There was a dramatic decrease in summertime bottom temperature in July 2005, coupled with bottom and sea surface temperatures which repeatedly reached over 30°C. Temperatures of 30°C and above are considered to signal the probable onset of bleaching for tropical corals, depending on the latitude of the reef system and seasonal maximum SST (Manzello et al. 2007). Further, Degree Heating Week (DHW) data, which is a proxy for thermal stress and represents the number of weeks during which the average weekly sea surface temperature is greater than the expected average monthly maximum temperature, also showed 2005 to be remarkable in the temperature regime over Stetson Bank (for a more thorough explanation of DHW, see http://coralreefwatch.noaa.gov/satellite/methodology/methodology.html#dhw). Specifically, compared to 2004, with 24 weeks at 0.55 DHWs, there was a dramatic increase to 32 weeks at a maximum of 6.05 DHWs in 2005. In 2006, there were only 6 weeks at

0.5 DHW; 2007 increased to 25 weeks at 0.8 DHW. As of September, there were no DHW in 2008 (data courtesy of NOAA Coral Reef Watch).

Coupled with the high, prolonged temperatures of 2005, coastal runoff from the passage of Hurricanes Katrina and Rita also reached Stetson Bank. Though Stetson Bank is subject to repeated influxes of freshwater, none of the documented influx events between 2004 and 2008 rivaled the events which occurred in 2005. The lower salinity regime instigated by two hurricanes passing through the northern Gulf of Mexico lasted several weeks, from August to October (see Fig. 5). Though water quality was not specifically tested at the FGBNMS, this plume of freshwater originating from the Gulf Coast and Mississippi River and driven southwestward by the winds of Hurricane Rita and spinoff eddies from the Loop Current, might have carried pollutants, chemicals, and nutrients to an already stressed reef community (see Rabalais et al. 1996; for review of effects of coastal discharge on corals, see Fabricius 2005).

The lack of quick recovery of *Millepora* following the bleaching event might be attributed to the dependence of the population on larval recruitment, rather than colony regrowth. Due to the severity of the 2005 bleaching event, most *Millepora* colonies exhibited total mortality, so that regeneration from remaining live tissue was not possible. An initial image assessment of a subset of randomly selected photostations exhibited only one or two new colonies between 2007 and 2008. *Millepora* spawning has not been reported from the FGBNMS, and little is known about its reproductive ecology (see Soong and Cho 1998). Depending on local *Millepora* behavior and larval duration, the resiliency of the *Millepora* population of Stetson Bank might depend on larval recruits from other coral communities in the Gulf of Mexico. However, there is limited research on the extent of population connectivity among the reefs and banks of the northwestern Gulf of Mexico (but see Lugo-Fernandez 1998; Lugo-Fernandez et al. 2001).

High seawater temperatures and major hurricane impacts (with associated freshwater influxes) in 2005, followed by an increase in recruitment-inhibiting macroalgae species (e.g., see Kuffner et al. 2006), and a dependence on larval recruitment, might explain why the reef community of Stetson Bank has not yet recovered to pre-bleaching benthic species assemblage patterns. However, as of 2008, the reef ecosystem of Stetson Bank may be exhibiting signs of resiliency, as evidenced by a subsequent decrease of macroalgae and an increase in coralline algae, the degree of which will be established through continued monitoring efforts.

3) Fujairah Municipality, Fujairah, United Arab Emirates

Abstract. In June 2007 Cyclone Gonu, the most powerful storm in the region in 60 years, impacted reefs in the United Arab Emirates along the Gulf of Oman coastline. The extent of destruction of the reef corals varied considerably depending on site, taxa and colony morphology. This study describes the short-term recovery of corals following the cyclone disturbance. Monitoring stations have been installed near the cities of Dibba and Fujairah. Each station consists of two primary components; (i) transect markers that create a three-ray pattern for repetitive photographic surveys, and (ii) a settlement plate rack with horizontal and vertical limestone tiles. Analyses of the transect photographs provide spatial and temporal comparisons such as coral area cover, colony size frequency distributions and colony growth rates. Examination of the settlement plates indicates coral larvae recruitment into the area, which may also indicate future shifts in community structure. Site data such as hourly seawater temperatures measured approximately 0.5m above the reef, sea urchin and crown-of-thorn starfish densities, and rugosity (topographic complexity) are evaluated in relation to the spatial and temporal patterns. While this study focuses on the short-term recovery of these reefs, future studies may continue to track their long-term progression at the permanent monitoring stations.

Key words: Cyclone Gonu, hurricane disturbance, recovery, Gulf of Oman.

Introduction

Coral communities in the eastern United Arab Emirates (northwestern Gulf of Oman) exist in shore-parallel patches and around rock islands. Coral cover in this area has typically been 30-40% at depths of 4-12m. The overall condition of corals in the Gulf of Oman had been relatively stable prior to June 2007. Upwelling mitigates elevated SST anomalies that lead to bleaching elsewhere and storm damage has been uncommon. On occasion, coral communities have experienced localized temporal variability due to crown-of-thorns starfish outbreaks and periodic recruitment episodes (Rezai et al. 2004).

In June 2007, Cyclone Gonu hit the Arabian Peninsula as the strongest storm since recordkeeping began in 1945. Following such a disturbance, coral community structures are reshaped based on the recovery of the surviving colonies and the recruitment of new individuals into the community (Hughes 1989; Smith and Hughes, 1999; Riegl 2001; Loch et al. 2003; Lirman 2003; Golbuu et al. 2007; Guzman and Cortes 2007). Positive recovery outcomes include the continued growth of undamaged colonies, fragment reattachment, and remnant tissue regrowth on partial-mortality colonies. Negative recovery outcomes include subsequent mortality due to disease resulting from compromised colony health, transportation of fragments to unsuitable locations, and the collapse of reef framework resulting from bioerosion. Recruitment of new individuals may be the result of sexual reproduction of local surviving colonies or the immigration of larvae that have dispersed over long distances. Sexual reproduction of local surviving colonies may be negatively impacted by sublethal stresses that require increased energy expenditure for maintenance, repair and growth. Fecundity may be decreased and reproductive cycles may be interrupted, delayed or skipped in such colonies (Harrison and Wallace 1998).

The objective of this study was to compare the short-term recovery patterns between and among the coral communities offshore Fujairah and Dibba, UAE. Data collected from permanent monitoring stations shall be used to describe the community structures of the surviving colonies, as well as the recruitment patterns of new individuals into the population.

Methods

Monitoring stations were installed in areas representing various levels of disturbance along

coastal Dibba and Fujairah, United Arab Emirates. The monitoring stations consist of three replicate 10.0m x 1.5m belt transects in a three-ray pattern (Fig. 1). A settlement plate rack serves as the center point of the station. Three transect markers are cemented into the nearby reef, approximately 12m from the center marker and at 120° angles from each other. Temporary lines are strung from the center marker to each of the end markers to create the three rays of the star pattern. These transect markers ensure the repeatability of photographs and benthic measurements (i.e. rugosity, slope, depth, sea urchin abundance) by marking the start and end points of the surveys.

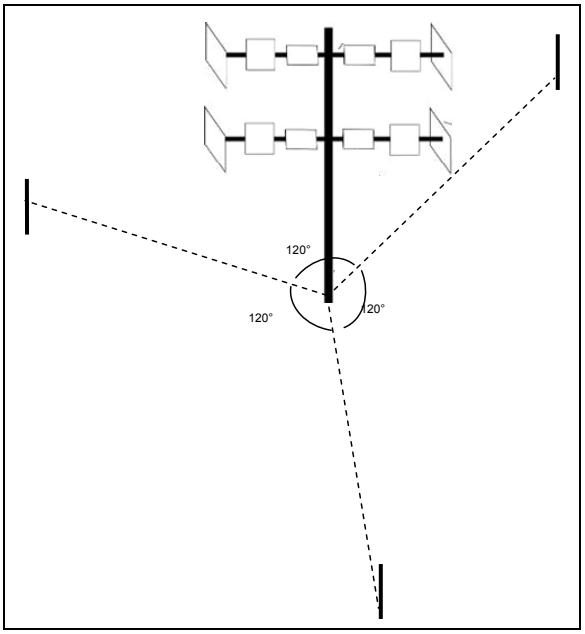

Figure 1: Three-ray monitoring station design. A settlement plate rack serves as the center point. Transect markers are permanently cemented into the reef to create the three rays of the star pattern.

Limestone or terra cotta tiles (10cm x 10cm x 1 cm thick) were attached to the settlement plate rack. The tiles were positioned (i) horizontally, (ii) vertically and parallel to the rack, and (iii) vertically and perpendicular to the rack. Tiles in positions (i) and (ii) were in pairs to create unshaded upper and shaded lower surfaces as well as cryptic space in the gap between the tiles. Tiles will be replaced annually and examined for coral spat.

Digital images were be taken along each of the transect rays using housed Olympus C-750/C-770 cameras (4 mega pixel) and 16 mm wide-angle conversion lenses set 50 cm above the reef inside rigid photo-framers. These photographs were analyzed for hard coral area cover. Image mosaics were created and individual colony surface areas were be traced and color coded by species to create a visual representation of each transect ray for spatial and temporal comparisons. The hard corals in each photograph were identified to species and surface areas (planar view) determined using Coral Point Count with Excel extensions (CPCe) (Kohler and Gill 2006). The data to be derived from CPCe included percent live coral cover, coral density as individuals per m^2, number of species present, average colony size, size frequency distribution, and diversity indices.

Results

The cyclone disturbance had varying effects on the coral communities depending on site, taxa and colony morphology. The initial assessment of the four monitoring stations in August 2007, two months following Cyclone Gonu, indicated that resilient taxa (i.e. faviids and poritids) were minimally damaged, while the susceptible taxa (i.e. acroporids and pocilloporids) were moderately to heavily damaged. The least damaged sites, Dibba South (DIBB2) and Mirbah North (MIRB1), included areas with massive colonies of *Platygyra* and *Favia* spp. that survived relatively unscathed, showing little or no signs of scouring or partial mortality. Dibba Rock (DIBB1) was a moderately damaged site that included areas of dense monospecific stands of *Pocillopora damicornis* from which individual colonies were dislodged or broken. Mirbah South (MIRB2), an area that had been dominated by tabular *Acropora clathrata,* was the most severely damaged site with large sections being completely razed.

Benthic data collected from the monitoring stations in August 2007 are shown in Table 1. Rugosity ratios (topographical complexity) measured 1.1-1.2, indicating the near flattening of reefs (1.0 indicates a horizontal surface). Live coral cover ranged between 24-45%, primarily due to the survival of massive colonies and the presence of detached fragments with live tissue. Coral densities varied between sites (5.2 – 33.3 colonies per m^2), with higher densities being the result of extensive breakage and fragmentation of branching and bushy colonies. The average colony surface area ranged between 98-452 cm^2, with the lower averages occurring at sites with extensive fragmentation.

Between 7-14 species were inventoried along the transect rays at each site (Table 2). This was higher than anticipated, based on previous site visits, because less common cryptic taxa were now obvious due to the removal of the branching and bushy coral overstories. Four species of massive scleractinians (*Favites pentagona, Platygyra daedalea, Porites lutea, Siderastrea savignyana*) were present at all four monitoring stations.

Table 1: Benthic data collected at monitoring stations in August 2007. Sites are presented from north to south, with DIBB1 being the northernmost site and MIRB2 being the southernmost site.

	DIBB1	DIBB2	MIRB1	MIRB2
Rugosity Ratio	1.1	1.2	1.1	1.1
Live coral cover (%)	45	24	30	33
Coral density (colonies per m^2)	18.7	5.2	9.5	33.3
Average colony surface area (cm^2)	239	452	314	98
Sea urchin density (individuals per m^2)	0.6	2.2	0.6	0.0

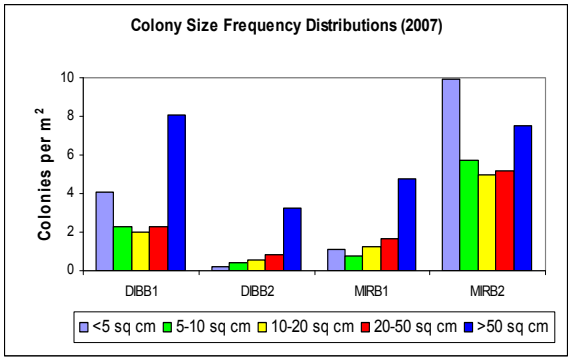

Figure 2: Colony size frequency distributions in August 2007. Large massive colonies (>50 cm^2 diameter) survived at all stations. Large fractions of small individuals (<5 cm^2 diameter) were present where extensive fragmentation occurred during Cyclone Gonu.

Size frequency distributions demonstrated the survival of the large massive colonies (>50 cm^2 diameter) at all monitoring stations (Figure 2). Large fractions of small individuals (<5 cm^2 diameter) were present at DIBB1 and MIRB2 where extensive fragmentation of *Pocillopora* and *Acropora*, respectively, occurred during Cyclone Gonu.

Sea urchin densities ranged from 0.0-2.2 individuals per m^2 along the transect rays (Table 1). Multi-year sampling shall indicate if this is a normal population or if the abundance was reduced by the cyclone. Sea urchin densities are important as these herbivores maintain the standing algal crop that may otherwise outcompete coral recruits for available substrate.

No crown-of-thorn starfish (COTS) were observed along the transect rays or within the general vicinities of the monitoring stations. COTS have been shown to preferentially feed on branching taxa (McClanahan et al 2005). Therefore, the presence of COTS may influence the recovery of taxa that are also susceptible to mechanical damage from cyclones (i.e. acroporids and pocilloporids). If COTS are observed in subsequent surveys, COTS densities shall be calculated for each site and compared with recovery patterns for branching taxa.

Discussion

The results presented herein are from the first of several surveys to be conducted in order to compare the short-term recovery patterns between and among the coral communities offshore Fujairah and Dibba, UAE. Rugosity and coral cover may increase over time if fast-growing species (i.e. acroporids and pocilloporids) recover quickly. Coral densities may fluctuate; increasing if recruits settle onto newly available substrate or decreasing if fragments are transported elsewhere by water movement. Taxa inventories may change with the settling of additional species from distant larval sources or if localized extinctions occur from post-storm circumstances such as algal competition or disease outbreaks. Size frequency distributions are expected to vary primarily based on the outcomes of the *Acropora* and *Pocillopora* fragments since the massive colonies, which grow at rates of ~1 cm per year, are unlikely to move between size classes for the duration of this study. The skewness in size frequency distributions can indicate trends in recruitment, survival and growth of coral communities. Communities skewed to the left (i.e. mostly larger colonies) may indicate strong survival of massive colonies with poor post-disturbance recruitment. Communities skewed to the right (i.e. mostly smaller colonies) may indicate extensive fragmentation or heavy recruitment.

While this study focuses on the short-term recovery of these reefs, future studies will track long-term progression at the permanent monitoring stations.

Bathymetric Distribution of the Benthic Marine Flora in Chemuyil, Mexico

A. González-Solis[1], D. Torruco[1]

CINVESTAV-I.P.N. Km 6 Carretera a Progreso, A.P. 73, C.P. 97310, Merida, Yucatan, Mexico

Abstract. 34 species of benthic marine flora between 0.5 and 35 ms of depth were determined, species with the greatest dominance was: *Enteromorpha flexuosa, Halimeda incrassata, Coralline articulate, Lobophora variegata* and *Galaxaura oblongata, E. flexuosa* was the most common. The sampling methodology was based on 117 phototransects to different depths. The index of diversity and density increased with the depth. The most frequent species with relative abundance bigger than 10% were *E. flexuosa* and *H. incrassata*. In this work the importance of some ecological attributes in the bathymetric distribution for this group was analyzed. The depth with greater diversity was registered at 3 m. The analysis of assemblaje gives a high associations among stations, their diversity and specific richness, which evidence the importance of such factors as: depth, light availability, substratum, wave effect, sedimentation and environmental conditions, among others.

Key words: algae, macroflora, distribution, biodiversity, Yucatan.

Introduction

The vegetation is one of the main components of coralline reefs with multiple functions, one of the most significant is the stabilization of substratum, because it is the nutritional resource of a great number of herbivorous and a fixing device of vital elements such as nitrogen, which recycles and makes it available for other groups. Some genus, such as *Halimeda* and *Penicillus* deposit aragonite (as $CaCO_3$) forming sand and sediment, participate actively in the reef formation or in change processes.

In reef ecosystems, marine flora is represented by macro algae which are a group with high diversity. It is important to evaluate reef communities with emphasis in the structure of their populations, information necessary to formulate accurate hypotheses of the relation between the biotic and abiotic factors of these environments (Liddell and Ohlhorst 1991). Also, the present study analyzes the composition and space distribution of the macroalgae in the coralline reef of Chemuyil, Quintana Roo at different depths.

Material and Methods

Study Area. The reef of Chemuyil is a barrier located 115 km from Cancun in the coast of the State of Quintana Roo, Mexico. It is part of the northwest region of the Caribbean zoogeographic province (Fig. 1).

Sampling. The sampling took place by means of an annual cycle from 2006 to 2007, with 117 photographic transects of 20 m of length (Liddell and Ohlhorst 1991, Torruco 1995) and stations each meter, work was performed in 14 depths of the reef between 0.5 and 35 m. At the same time, a selective collection was made for its identification in the laboratory (Taylor 1960, Litter et al. 1989) and it was used as base of reference for the photo-interpretation.

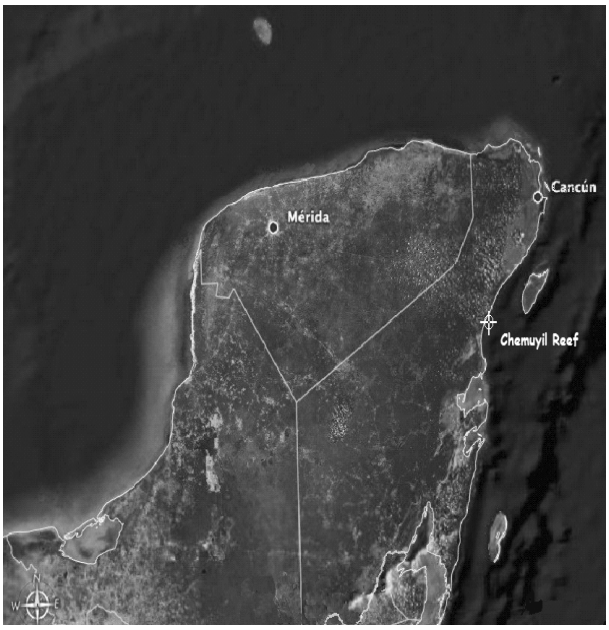

Figure1. Map showing the Chemuyil Reef, Quintana Roo, Mexico.

Analysis. The Dominance analysis was determined following Orlóci hierarchic criterion (Orlóci, 1978), the diversity was evaluated by means of the index of Shannon-Wienner (Magurran, 1988) and eveness with the equation of Pielou (1984). In the cluster analysis the index of similarity of Bray-Curtis was used with Lance and Williams criterion of flexible union with a β=0.25 (Orlóci, 1978). The discrimination of the species by depth was evaluated with the divisive analysis of arrangement using the content of information of order 2 (Ezcurra and Equihua, 1984).

Results

A total of 34 species of benthic marine flora between 0.5 and 35 m were determined. The ten more dominant species were: *Enteromorpha flexuosa* (16.54), *Halimeda incrassata* (15.55), *Lobophora variegata* (8.58), *Galaxaura oblongata* (8.45), *Dictyota divaricata* (6.31), *Amphiroa rigida* (4.86), *Halimeda opuntia* (4.32), *Caulerpa racemosa* (3.03), *Centroceras clavulatum* (2.77) and *Dictyota dichotoma* (2.45).

The highest specific richness was registered at 6 m of depth (S=12); followed by 3 m, 5 m and 35 m (S= 11), the lowest one appeared at 32 m (S= 4). Also, the most diverse depth corresponded to 6 m with H= 2.98 bits/ind and the lowest to 3 m with H= 1.23 bits/ind. In the eveness the pattern was the same, the highest at 6 m (E= 0.83) and the lowest at 3 m (E= 0.35, Fig. 2).

The similarity analysis registered three assemblajes at higher levels than 80 %. The first one at a 0.9 level links to 6 and 18 m depths, stations characterized by their high specific richness (S= 12 and 10 respectively) and diversity (H= 2.98 and 2.6 bits/ind). The second at a level of 0.85 associated mainly by the proximity of depth to the 13 and 14 m, with a variable specific richness (S= 6 and 10 respectively) and an intermediate diversity (H= 1.74 y 1.86 bits/ind).

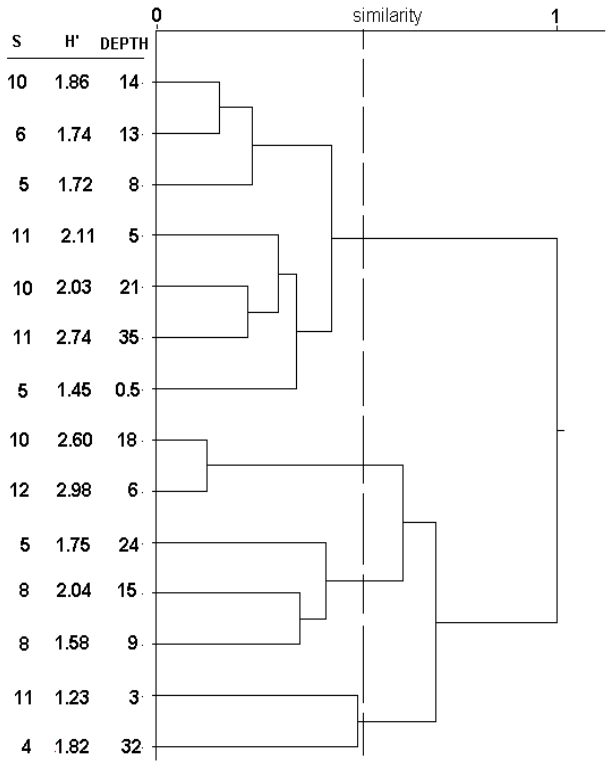

Figure 2. Cluster analysis of depth similarity, richness of species and diversity in Chemuyil Reef, Quintana Roo, Mexico.

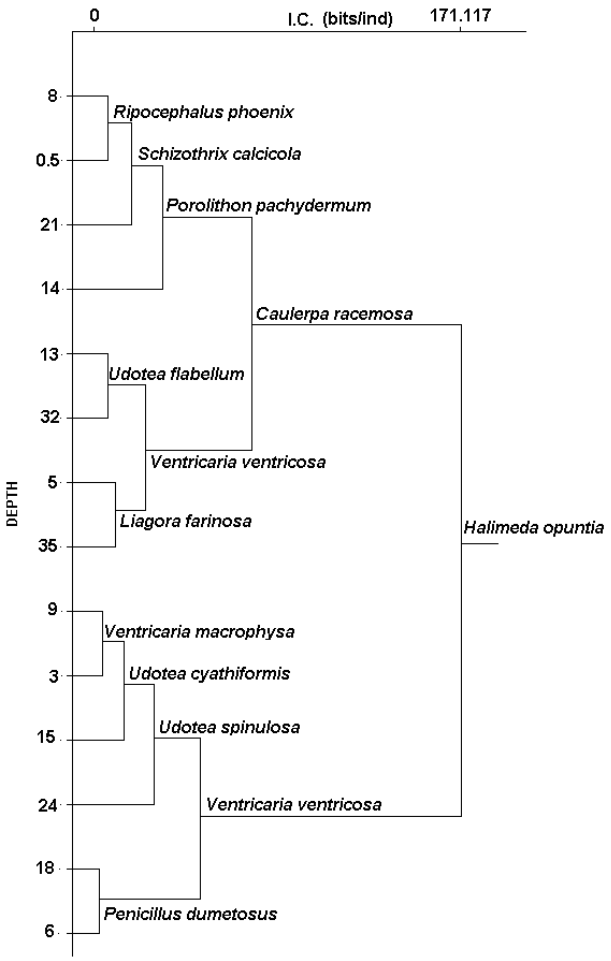

Figure 3. Cluster analysis of macroflora by discriminate the species in Chemuyil Reef.

The third at 0.80 level associated to high depths: 21 and 35 m, was characterized to register high specific richness (S= 10 and 11 respectively) and diversity (H= 2.03 and 2.74 bits/ind). These associations evidence high diversity and specific richness in the reef at high depths (Fig. 2).

The analyses of assemblage by depth to discriminate the species are shown in figure 3. The seven indicating species of the discrimination between the levels 0.07 to 0.87 are in sequential order: *Halimeda opuntia, Caulerpa racemosa, Ventricaria ventricosa*, *Porolithon pachydermum*, *Udotea spinulosa*, *U. cyathiformis* and *Schizothrix calcicola*. *Liagora farinosa* was the indicating species at 0.9 level and at greater levels than 0.93 the discriminating species were: *Ripocephalus phoenix*, *Udotea flabellum*, *Ventricaria macrophysa* and *Penicillus dumetosus*, this last species associated to the depths of 6 and 18 m, characterized by its high diversity and specific richness.

Discussion

The marine benthic macroflora of the barrier of Chemuyil was less diverse in comparison with other reefs areas of the region (Table 1). This result can be because the comparative one was made with protected natural zones, which provides a greater diversity and abundance. Other causes can be the sampling method used or a greater competitive pressure, due to the ample coralline development of the area.

Table 1. Comparison of the richness in the touristic corridor Cancun - Tulum. C= Chlorophyta, P= Phaeophyta, R= Rodophyta and S= Sorce.

Chemuyil	17	7	10	This Work

Great part of the coast of Quintana Roo, is a combination between sandy and rocky beaches, specially the shallow reef areas, which originates an ample variety of habitats. The analysis registered an ample development of coral scleractinian in the platform, between their furrows and crests (63 % of the total area), reason why a competitive pressure with the macroflora is considered. The most conspicuous species were the calcareous forms of red algae, which reached 5 %, the total coverage of the group in the reef was of 24 %. Gutierrez-Carbonel et al. (1995) reports in the Reserve of the Biosphere of Sian Ka' an greater coverage (50 to 65%). The registered assemblies provide greater stability, the obtained pattern of high richness and diversity appeared to high depths and decreases towards intermediate depths. The indicating species of the state of health of the macroflora in Chemuyil were: *Enteromorpha flexuosa* and *Halimeda opuntia*.

Other authors (Cramer 2008, Gilner and Van Woesik 2008, Venera-Ponton et al. 2008), mention that the reefs of the Caribbean are being transformed into algae reefs; however the reef of Chemuyil registered a greater coralline development between the 30 and 40 ms of depth, although it is certain that the greater richness and diversity of macroflora appeared to high depths, the percentage of coverage was minor to the one of the coralline coverage, reason why this asseveration must be referred to shallow zones. Consequently, the richness of species and the obtained patterns of diversity probably exhibit low registries, they increase as depth increases, due to the high rate of sedimentation registered in the shallow zones, which originates a reduction in their biodiversity.

Abstract. In the summer of 2005, the Caribbean region experienced a widespread coral bleaching event. In order to determine the extent and effect of this event on the reefs of Tobago, the Buccoo Reef Trust (BRT) and Coral Cay Conservation (CCC) conducted a targeted coral reef survey programme around the island between October and November 2005 as the first part of a two-phase campaign. In Phase I the reefs were assessed to establish their current status. In Phase II, a long-term monitoring programme was installed to record subsequent degradation or recovery of the reefs from the bleaching event. Results from Phase 1 found overall mean bleaching of hard corals to be 66%. Although most sites had greater than 85% bleaching, some local reefs on the northeast of Tobago had less then 20% bleaching, perhaps indicating localised tolerance. Bleaching was also found to be highly variable, both between and within species. Notably, *Acropora palmata* stands all appeared to be unbleached. No significant coral diseases were observed during Phase 1 surveys. Results from Phase 2 indicate a high prevalence of coral disease at many sites throughout the area. Yellow Band Disease was commonly seen on *Montastrea* species. There were also high levels of White Plague Disease and *Aspergillosis*. Initial findings suggest that disease were generally prevalent on reefs adjacent to areas of high coastal development and/or agricultural land use and prevalence was inversely related to depth.

Keywords: Coral, disease, bleaching, reef status, Tobago

Introduction

The coral reefs of Tobago, like many of those throughout the Caribbean region, are severely threatened (Gardner et al. 2003) and the overriding cause is thought to be human activity (Mora 2008). Threats to reef health include overfishing, habitat degradation, land-based pollution stresses and climate change induced events. The prevalence and types of coral disease in the Caribbean have been well documented (Antonius 1981; Goreau et al. 1998; Green and Bruckner 2000; Smith et al. 1996; Sutherland et al. 2004). Tobago has been no exception with serious disease outbreaks in the past e.g. Laydoo (1983).

The large-scale bleaching event of 2005 is an example of a major climate change induced event that significantly affected Tobago's coral reefs (see Wilkinson and Souter 2008). In order to determine the extent and effect of this event on the reefs of Tobago, the Buccoo Reef Trust (BRT) and Coral Cay Conservation (CCC) conducted a targeted coral reef survey programme at 22 sites around the island between October and November 2005.

A two-phase campaign was launched. In Phase I the reefs were assessed to establish their current status. In Phase II, a long-term monitoring programme was installed in order to monitor the reefs to record subsequent degradation or recovery from the event.

Results from Phase 1 found overall mean bleaching of hard corals to be 66% (O'Farrell and Day 2005). Bleaching levels in Tobago were found to be consistent with regional results, with most Tobagonian sites exhibiting greater than 85% bleaching. However, some local reefs on the northeast of Tobago had less then 20% bleaching, perhaps indicating localised tolerance. Bleaching was also found to be highly variable, both between and within species. Notably, *Acropora palmata* stands all appeared to be unbleached. No significant coral diseases were observed during Phase 1 surveys although a few diseased coral colonies were observed in north-west Tobago in 2003 including White Band, Yellow Band (Blotch) and Black Band Disease (Lapointe 2003).

Following the successful partnership in 2005 CCC and the BRT established a programme of

study in collaboration with the Tobago House of Assembly and with the support of the United Nations Development Programme Global Environment Fund (UNDP-GEF). Part of this study, the Tobago Coastal Ecosystem Mapping Project (TCEMP), began in March 2007 in north-west Tobago (Fig. 1) with the three main objectives to:

1. Provide baseline data on the status of Tobago's coral reef, mangrove and seagrass ecosystems;
2. Increase awareness about Tobago's marine resources through educational programmes;
3. Build in-country capacity through scholarship programmes.

The data collected during the TCEMP will be used by the Integrated Watershed and Coastal Area Management (IWCAM) Caribbean programme to provide relevant information to the Government of Trinidad and Tobago in order to enable effective coastal zone management.

Methodology

Coral Disease Studies

Anecdotal observations suggested that coral disease prevalence had become a more serious contributor to coral reef degradation in Tobago following the 2005 bleaching event. To document this phenomenon, monitoring of the prevalence and severity of common and easily identifiable coral diseases was initiated in 2007. Here we present some initial trends for diseases recorded during CCC baseline surveys. Monitoring stations of tagged coral colonies were also set up in order to collect quantitative data on the rate of coral disease infestation. Full details of the survey methods used are provided in the report by van Bochove et al. (2008).

Results

All data presented was collected on CCC baseline surveys between May 2007 and June 2008 along the north-western coast of Tobago between the Buccoo Reef complex and Castara (Fig. 1). Four coral diseases, Yellow Blotch Disease (YBD), White Plague (WPL), Dark Spot Syndrome (DSS) and Aspergillosus (ASP), were recorded most often on surveys conducted at 7, 12 and 16 metres depth (Table 1). Other coral diseases that were recorded occasionally were Black Band Disease (BBD), White Band Disease (WBD), White Pox (WPD) and Patchy Necrosis but data for these diseases are not presented here.

Table 1. Coral species affected by four main diseases in north-west Tobago.

Disease: Species	Yellow Blotch	White Plague	Dark Spot	Asper-gillosus
Colpophyllia natans		M, D		
Dichocoenia stokesii			M	
Diploria strigosa	S, D	S, M		
Gorgonia ventalina				S, M, D
Millepora sp.	D			
Montastraea spp.	S, M, D	M, D	M	
M. faveolata	S, M, D	S, M, D		
M. franksi	S, M, D	S, M	D	
M. cavernosa	S, M, D	S, M	D	
Porites asteroides		S, M, D		
Siderastrea radians			S	
Siderastrea siderea		M, D	S, M, D	
Solenastrea hyades	D			

Where: S = Shallow (7 m), M = Medium (12 m), D = Deep (16 m).

Ten species of hard corals, one hydrozoan and one gorgonian were affected by the four main coral diseases (Table 1). A number of genera were infected by more than one disease at a range of depths (e.g. *Montastraea* and *Sideastrea*). Others were only affected by one disease type such as *Porites asteroides* (WPD) and *Gorgonia ventalina* (ASP).

Coral disease prevalence for the four main diseases is presented in Figure 2 for three depth bands (7, 12 and 16 metres) as a mean percentage value for all the coral types affected. The proportion of coral colonies affected by YBD,

WPL and DSS appear to be inversely related to depth, with the highest levels recorded at the shallowest depth band surveyed (7 m).

This decrease with increasing depth is most obvious for DSS where disease prevalence decreases from 67% to 23%. The highest levels of disease prevalence were recorded for common sea fans with *Aspergillosus* (72%) Infestation levels were all greater than 60% of coral colonies at the shallow depth band (7 m).

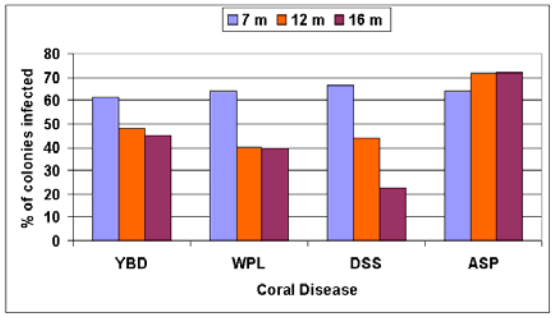

Figure 2: Coral disease prevalence in all coral types at three depth bands in north-west Tobago

Looking at two hard coral genera in detail, coral disease data for *Montastraea* and *Siderastrea* indicates that each genus is mainly affected by two types of disease (Figs. 3 & 4).

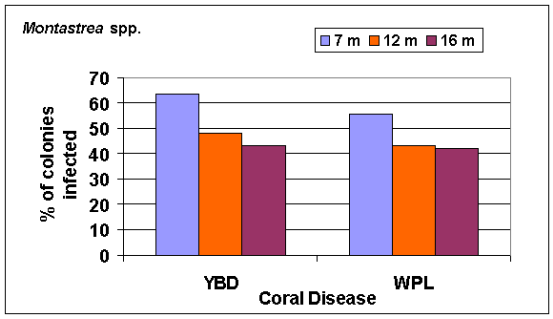

Figure 3: Coral disease prevalence in *Montastraea* spp. at three depth bands in north-west Tobago

Coral disease prevalence was generally higher in more shallow waters. More than 60% of *Montastraea* colonies were infected with YBD in shallow waters (7 m) with prevalence decreasing to 43% (16 m). Similarly prevalence of DSS in *Siderastrea* was high (67%) at 7 m. depth but dropped off markedly to 24% at 16 m (Figure 4)

Statistical comparison of disease prevalence for *Montastraea* and *Siderastrea* colonies over the three depth bands and for three diseases (Table 2) revealed significantly higher percentages of colonies infected in shallower waters for YBD in *Montastraea* and DSS in *Siderastrea* (One-way ANOVA and Two-tailed T-Test on arcsine transformed data).

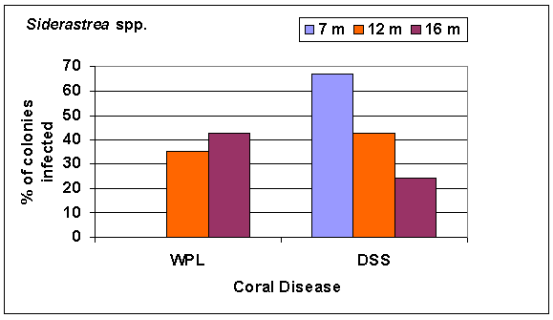

Figure 4: Coral disease prevalence in *Siderastrea* spp. at three depth bands in northwest Tobago

Table 2. Statistical comparison of coral disease prevalence for two coral genera and three diseases over three depth bands

2a – One-way ANOVA

Genus	Disease	P value
Montastraea	YBD	< 0.001
Montastraea	WPL	n.s.
Siderastrea	DSS	< 0.001

2b – Two-tailed T-Test

		Depth Comparison		
Genus	Disease	7 vs. 12	7 vs. 16	12 vs. 16
Montastraea	YBD	++	+	n.s.
Siderastrea	DSS	++	+++	++

Where: n.s. = not significant; + = $p<0.05$; ++ = $p<0.01$; +++ = $p<0.001$

Summary and Conclusion

Coral disease is certainly a serious issue for the fringing reefs of north-western Tobago and is likely to cause a further reduction in live hard coral cover for a region that is already suffering from high coral mortality, particularly after the 2005 bleaching event. Indeed the increase in coral disease prevalence since the bleaching event may be directly linked to the thermal stress experienced during 2005 in that climate-mediated, physiological stresses may compromise host resistance and increase frequency of opportunistic diseases (Harvell et al. 1999).

This study has indicated that coral disease prevalence for YBD and DSS appears to be related to depth with the percentage of coral colonies infected decreasing with increasing depth for *Montastraea* and *Siderastrea* respectively. At the shallow depth band (7 m) at least 60% of coral

colonies were infected by one or more disease for the coral species recorded. The positive relationship between depth and disease prevalence for certain combinations of genera and disease types may well be linked variation in water quality and land-based pollution (Bruno et al. 2003). Alternatively deeper corals are likely to have experienced less bleaching in 2005 and may therefore be less susceptible to infection.

Four main coral diseases (YBD, WPL, DSS and ASP) were recorded along Tobago's northern coastline. However, insufficient data was available at the time of writing to accurately compare coral disease prevalence on a spatial scale between reef sectors along the coast. There is also a need to conduct a temporal analysis of the data to determine whether disease prevalence is changing over time, especially since the last mass coral bleaching event. Further analyses will be undertaken as the TCEMP progresses and the dataset becomes more robust. An interesting future comparison will be to look at the level of coral disease prevalence between the north-west and north-east coasts of Tobago as the two areas differ in terms of population density and coastal development. The north-east coast was also less severely bleached than the north-west in 2005, which may also influence coral disease prevalence.

Acknowledgements

Coral Cay Conservation and the Buccoo Reef Trust would like to acknowledge the kind support and partnership of the Tobago House of Assembly in the TCEMP as well as all partners and supporters of the project both in the UK and the Caribbean, but particularly UNDP and the GEF Small Grants Program. CCC would also like to thank all the dedicated field staff and volunteers on the project site who enable the TCEMP to run effectively.

3) Department of Environmental Sciences, Swiss Federal Institute of Technology Zurich, Switzerland

Abstract. Rodrigues was one of the few reef locations in the Western Indian Ocean to escape the mass coral bleaching event of 1997 – 1998, however shallow reef sites have suffered from bleaching events in 2002, 2005 and 2007. In all 3 years, there were small-scale spatial variations in the severity of bleaching and associated mortality. Temperature data indicate small-scale variations in sea temperature around the lagoon and current data suggest that bleaching tended to occur in areas with the lowest current speeds. Recovery of sites from bleaching also showed small-scale spatial variations. Inshore sites, displayed limited recovery to the beaching events and sites are dominated by turf algae (>60 %) with low live coral cover (<15 %), whereas live coral cover has increased at a site further offshore. This variation in recovery is likely to be due to the proximity to land and increased human impacts. This suggests that if coral bleaching events continue to occur on a regular basis then these inshore reefs could become overgrown by algae and their structural complexity eroded. Rodrigues is a small, isolated island with a limited coral larval supply and such a scenario would leave the island vulnerable to coastal flooding and storm damage.

Key words: coral bleaching, mortality, recovery, sea surface temperature, Indian Ocean

Introduction

Rodrigues is a semi-autonomous island forming part of the Republic of Mauritius, located 560 km north east of the main island in the western Indian Ocean. The island is surrounded by 90 km of fringing coral reef, which creates a shallow lagoon of 240 km^2. One hundred and sixty species of coral have been recorded in Rodrigues (Fenner et al. 2004) and the fore reefs have high live coral cover (30 – 50 %) at 6 – 12 m depth (Shoals Rodrigues unpublished data).

The coral reefs of Mauritius and Rodrigues were some of the few reef areas in the Indian Ocean to escape the mass coral bleaching event of 1997 - 1998 (Turner et al. 2000). However, unusually warm and calm conditions occurred during February 2002 resulting in coral bleaching, particularly at sites in the north and west of Rodrigues (Hardman et al. 2004). Surveys showed that although the bleaching was not widespread, it was severe where it did occur, resulting in mortality of up to 75 % of corals at some sites. Further coral bleaching occurred in 2005. Bleaching was again most severe in the north and west of the island, where up to 50 % of coral bleached, although mortality was not so severe as in 2002 (Hardman et al. in press).

This study investigates whether further coral bleaching occurred during 2007, following another period of warm, calm weather in January of that year. It also examines spatial variations in the recent coral bleaching events and subsequent recovery of affected sites.

Methods

Coral bleaching

Rapid assessment surveys were carried out at 26 sites around the island during June and July 2007 (Fig. 1). Sites were identified on the reef flat, reef slope and on the patch reefs within the lagoon.

Surveys were carried out using snorkelling techniques by a team of 2 - 3 personnel. Surveys on the reef flat were carried out at high tide so that surveyors could swim into the lagoon over the reef front and thus assess bleaching on the reef slope down to a depth of 5 – 6 m. Surveyors swam across the reef area for two minutes and then stopped and recorded the occurrence of bleaching within an area of approximately 5m x 5m. This was repeated to give a total of 20 observations per site. During each observation for each coral genus observed, the abundance of the genus and the percentage of colonies of that genus that was recently dead (still standing, but covered in a thin layer of turf algae), bleached (pale to completely bleached) and healthy was recorded on a 6-point semi-quantitative scale (0 = 0 %; 1 = 1 – 10 %, 2 = 11 – 30 %, 3 = 31 – 50 %, 4 =

51 – 75 % and 5 = 76 – 100 %) (Turner et al. 1999). The bleaching values for each genus were then averaged and multiplied by the abundance score for that genus to give a bleaching score for each coral genus observed. These values were then averaged to produce a mean bleaching value for each site.

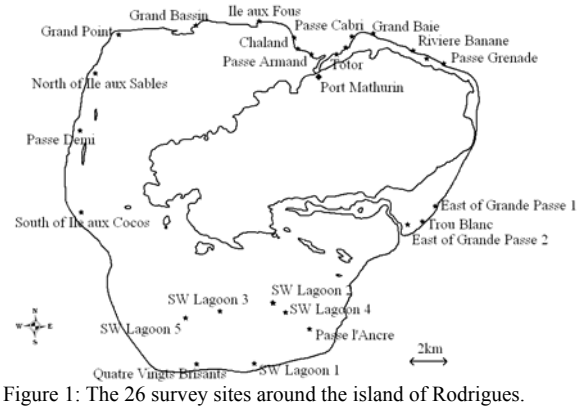

Figure 1: The 26 survey sites around the island of Rodrigues.

National Oceanic and Atmospheric Administration (NOAA) Sea Surface Temperature (SST) Hotspot charts and meteorological data (temperature, SST and sunshine hours) obtained from the Mauritius Meteorological Services were studied to identify annual large-scale variations in environmental conditions. Smaller scale spatial variations were investigated using data collected by Shoals Rodrigues. Continuous temperature loggers were placed on the reef flat at 3 sites in the north of Rodrigues (Totor, Grand Bassin and Ile aux Fous) between March 2006 and December 2007 and recorded SST every hour. Data on current speeds around the lagoon, collected using drogue buoys in 2002, were also analysed.

Recovery from bleaching

Additional detailed surveys were undertaken at three sites, which had been worst affected by the 2002 and 2005 bleaching events: Totor, Passe Armand and Ile aux Fous. All surveys were undertaken on the reef flat at depths of approximately 1 m. Three 20 m transect lines were laid parallel to the reef edge and separated by a distance of 10 m. Benthic community was assessed along each of the transects using the line intercept transect method (English et al. 1994). The abundance of coral recruits (colonies <10 cm in diameter) was also assessed by counting all of the colonies within thirty 0.25 m^2 quadrats randomly placed along the transects. These data were compared with similar surveys undertaken in 2003 (Hardman 2004) and 2006 (Stampfli 2006) to assess recovery over time.

Results

Coral bleaching

Recent coral mortality was observed on one patch reef in the southern lagoon (SW Lagoon 5). At this site, 100% of branching and tabular *Acropora* spp. were dead and had been recently colonised by turf algae. Live coral cover was <1 % and consisted of small encrusting and massive coral colonies (*Goniastrea* sp. and *Cyphastrea* sp.) as well as *Fungia* spp. Nearby patch reefs (<1 km away) were not affected by this bleaching and no other coral bleaching was observed. Indeed, at 95% of the sites surveyed during 2007, 76 – 100 % of coral colonies were healthy and showed no sign of bleaching or recent mortality.

NOAA SST charts indicate that Hotspots values were 1.0 ^oC above the climatological maximum from 16th until 26th March 2002; >1.0 for a 1-month period from 26th February until 26th March 2005 and were >0.5 from 26th January until 20th February 2007 (NOAA/NESDIS/OSDPD 2008). Meteorological data indicate that maximum sea temperatures >30 ^oC were recorded in February 2002, March 2005 and January 2007 (Fig 2). Maximum air temperatures were above the long-term mean (1971 - 2000) during January - March 2002 and 2005 and during January 2007; hours of sunshine were above the long-term mean during February 2002, January 2005 and January 2007 and wind speeds were below the long-term mean during January and February 2002, March 2005 and February and March 2007.

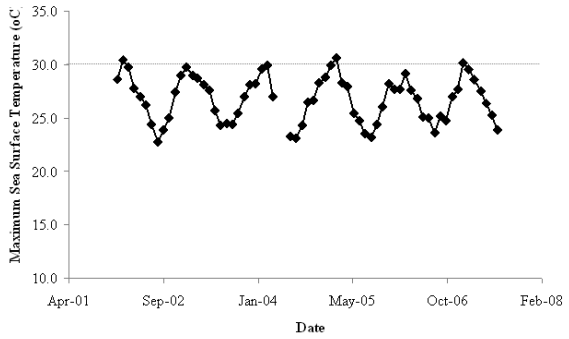

Figure 2: Sea surface temperature (SST) data for the Rodrigues lagoon from January 2002 – July 2007. Data provided by the Mauritius Meteorological Services.

Data from the continuous temperature loggers suggest that there are small-scale variations in SST around the lagoon and mean SST was significantly higher at Passe Cabri that at Grand Bassin and Ile aux Fous (1-way ANOVA, $p < 0.001$). Current speeds ranged from 0.48 m. s^{-1} in the southern lagoon to <0.1m. s^{-1} in the Port Mathurin Bay area and were significantly higher in the southern lagoon (mean: 0.27 m. s^{-1}) compared to the northern lagoon (mean: 0.18 m. s^{-1}) (T-Test, $p < 0.05$).

Recovery from bleaching

In 2007, the sites at Totor and Passe Armand were dominated by turf algae (>60 %) with low live coral cover (<15 %). In contrast, Ile aux Fous had a live coral cover of 21% and was dominated by coralline algae (49 %). The abundance of coral recruits varied from 2.0 ind. m^{-2} at Totor to 13.2 ind. m^{-2} at Ile aux Fous.

Passe Armand and Totor showed no change in live coral cover over time (Fig 3). The percentage cover of turf algae increased from 57 % in 2003 to 68 % in 2007 at Passe Armand and from 34 % in 2006 to 65 % in 2007 at Totor. At Ile aux Fous, live coral cover increased from 14 % in 2003 to 21 % in 2007; rubble fell from 35 % in 2003 to 0 % in 2007 and coralline algae increased from <1 % to 49 %.

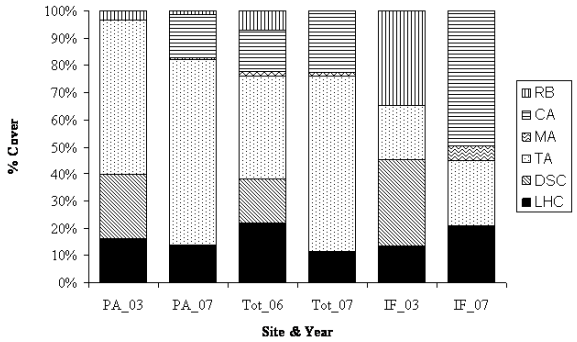

Figure 3: The percentage cover of 6 benthic categories at Passe Armand (PA), Totor (Tot) and Ile aux Fous (IF) during 2003, 2006 and 2007 assessed using the line intercept transect method.

Discussion

Coral bleaching

The data from 2002, 2005 and 2007 highlight small-scale variations in coral bleaching around Rodrigues. In both 2002 and 2005, sites in the north and west of the island were most severely affected. In 2002, 50 – 100 % of branching and tabular *Acropora* spp. died at 5 sites in the north of the island, whereas sites in the south and east were either healthy (no bleaching) or suffered from partial bleaching on the upper surfaces of branching colonies only (Hardman et al. 2004). In 2005, >50 % of coral colonies bleached at 10 sites in the north and west of the island and coral mortality occurred at 1 site, whereas bleaching in the south and east was mild and patchy (Hardman et al. in press). This study found that coral bleaching had occurred on just 1 patch reef in the southern lagoon, whereas sites <1 km away did not suffer from bleaching-related mortality. Coral bleaching was most widespread during 2005, but subsequent mortality was greater during 2002. In all cases, coral bleaching occurred at depths of <2 m and branching and tabular *Acropora* spp. were most severely affected. Previous studies have also shown that this genus is the most susceptible to coral bleaching and subsequent mortality (e.g. Brown and Suharsono 1990; Edwards et al. 2001; McClanahan 2004).

Data from NOAA and the Mauritius Meteorological Services suggest that conditions were conducive to coral bleaching during 2002, 2005 and 2007. SST data indicates that 30°C may be the threshold for coral bleaching in Rodrigues, as this was recorded during February 2002, March 2005 and January 2007, but not in years when bleaching did not occur. This is higher than the threshold of 27.5°C recorded in Mauritius (McClanahan et al. 2005), highlighting geographical variations in bleaching response. During February 2002, high air and sea temperatures, high hours of sunshine and low wind speeds all combined to promote heating of shallow water and increased solar penetration and thus explains the more severe bleaching observed during 2002. Although temperatures were high, sunshine hours were below average during March 2002 and wind speeds were above average during January 2007. Furthermore, in 2007, temperatures fell below average in February and March and February had very low cloud cover accounting for the limited bleaching that was observed during that year. This indicates that a combination of climatic factors, not just high temperature, is required for widespread coral bleaching to occur (e.g. Brown and Suharsono 1990).

Data from Shoals Rodrigues indicates small-scale variations in environmental conditions within the lagoon. SST varied significantly at sites 3 – 5 km apart and was found to be highest at the most inshore, sheltered site of Totor and lowest at the more exposed site of Grand Bassin. Totor was one of the worst affected sites in 2005 where 31 – 50 % of coral colonies bleached (Hardman et al. in press) whereas, although bleaching occurred at Grand Bassin in both 2002 and 2005, it was less severe (Hardman et al. 2004; in press). Current speeds were lower in the north of the lagoon than the south, suggesting that the decreased water flow may have increased the severity of coral bleaching at sites in the north and west of the island during 2002 and 2005. Environmental stress to corals has been shown to be reduced with high water flow whereas in areas of decreased water flow, oxygen accumulates within the coral tissues, resulting in oxidative stress and an increased severity of bleaching (Finelli et al. 2006). In contrast, McClanahan et al. (2005) show that in Mauritius, coral bleaching was positively associated with high water flow, with the most severe bleaching occurring on windward sites with the highest current speeds. They suggest that corals living in stable, less environmentally stressed environments such as these are more susceptible to bleaching increases. This may explain the bleaching in 2007, which occurred on the

southern patch reef only, a site with the highest current speeds, which had not exhibited bleaching in previous years.

Recovery from bleaching

Recovery from the bleaching events also showed small-scale variations with sites <5 km apart demonstrating different responses. Totor and Passe Armand have shown limited recovery 2 and 5 years respectively after suffering from bleaching-induced mortality and sites were dominated by turf algae with low live coral cover. In contrast, Ile aux Fous showed an increase in live coral cover, a high cover of coralline algae and the highest abundance of new coral recruits, indicating more successful recovery. Totor and Passe Armand are inshore sites (500m offshore), situated within the sheltered Port Mathurin Bay. These sites are subjected to high sedimentation, especially following periods of heavy rainfall (Hardman 2004), increased nutrient input (Shoals Rodrigues unpublished data) and human impacts such as trampling damage from octopus fishers.

The variation in recovery rates is therefore likely to be as a result of these additional human impacts. Lambo and Ormond (2006) also suggest that in Kenya, coral bleaching, sedimentation and fishing pressure have combined to result in further declines in live coral cover following the 1997/1998 coral bleaching event. Totor also has a high abundance of the bioeroding sea urchin, *Echinometra mathaei* (Hardman et al. in press) and bioerosion rates may counteract up to 150 % of the total calcification at this site. This high level of bioerosion suggests that if reefs continue to be affected by coral bleaching then there may be a loss of the coastal protection function of the reef.

Although Rodrigues escaped the mass bleaching event of 1997/1998, coral bleaching events have occurred in 2002, 2005 and 2007 causing locally severe mortality. It has been predicted that coral bleaching events will occur annually by 2030 - 2050 (Hoegh-Guldberg 1999) and Sheppard (2003) estimates that reefs in the Indian Ocean will be affected every five years by 2010 - 2025, becoming ecologically extinct within the next 20 – 40 years. If coral bleaching events continue to occur on such a frequent basis, then this will affect the integrity of the reef structure causing breaks in the reef's protective barrier, leaving these areas vulnerable to wave action and resulting in increased coastal flooding and storm damage with loss of coastal habitats and significant damage to coastal properties.

Rodrigues is a very isolated island, which receives a limited larval supply, suggesting that the reefs rely on larval retention and self-seeding for population recovery. Although McClanahan et al. (2005) suggest that the lack of bleaching in 1997/1998 and the local climatic conditions mean that reefs in this region may be more resilient to temperate anomalies, the limited larval supply inhibits recovery, making reefs more susceptible to climate change-driven reef degradation (Graham et al. 2006). These inshore reefs, already affected by human impacts, are therefore at risk of suffering a phase-shift to an algal dominated community with the associated loss of structural complexity. Rodrigues is highly reliant on its coral reef resources for food, employment and coastal protection and a loss of reef structure could have very serious consequences for the future of this small island.

Abstract. Non-point source sewage pollution represents a major threat to coral reefs. Impacts are typically associated with chronic eutrophication, water turbidity, and microbes potentially pathogenic to corals. Sewage pollution can produce variable system- and species-specific responses, as well as cascading direct and indirect effects, that could result in major long-term phase shifts in coral reef benthic community structure. This study was aimed at characterizing the ecological condition of eight shallow-water (<5 m) Elkhorn coral (*Acropora palmata*) assemblages located across a non-point source sewage pollution gradient along the southwestern Puerto Rico shelf. Non-point source pollution was a key stressor structuring local coral reef communities. Long-term phase shifts have favored dominance by macroalgae and non reef-building taxa at inshore locations under chronic pollution. Non reef-building taxa correlated with fecal pollution indicators. *Acropora palmata* and crustose coralline algae (CCA) are dominant at offshore remote reefs. Coral reef degradation is already beyond the point of recovery at most inshore habitats. Coral reef communities within local Marine Protected Areas were also undergoing significant degradation as a result of variable impacts, including non-point source sewage pollution. There is a paramount need to implement adequate management measures to prevent further water quality degradation across the region.

Key words: *Acropora palmata*, Coral reefs, Non-point source sewage pollution, Puerto Rico

Introduction

Marine non-point source sewage pollution is a major cause of concern in coral reef communities. Negative sewage impacts have been mostly associated to eutrophication and turbidity (Pastorok and Bilyard 1985; Cloern 2001). Kaczmarsky et al. (2005) also documented a high prevalence of Black Band Disease and White Plague-Type II in coral colonies exposed to sewage. Coral survival rates (McKenna et al., 2001), as well as reef-building activity (i.e., skeletal extension rates), are highly susceptible to sewage impacts, although effects seem to be species-specific (Tomascik and Sander 1985; Spencer-Davies 1990). Sewage impacts often result in a combination of system- and species-specific responses, as well as cascading direct and indirect effects that could result in major long-term phase shifts in benthic community structure, favoring dominance by fleshy macroalgae and non reef-building taxa. Such phase shifts could be irreversible in long-term scales (Knowlton 1992; Hughes 1994). Sewage-associated eutrophication impacts can also result in an accelerated reef decline often due to a combination of synergistic impacts, mostly from sedimentation and turbidity (Meesters et al. 1998; Szmant 2002), as well as to recurrent pulses of increased biological oxygen demand and declining dissolved oxygen concentration that can create a hypoxic condition in coastal waters (Desa et al. 2005).

Sewage impacts can produce a major decline in the socio-economic value of coral reefs and associated communities due to the loss of ecological services (i.e., coastal protection, sinkhole of greenhouse gases, food-protein production, source of bio-active compounds), and reef aesthetics (i.e., SCUBA, snorkeling, educational excursions). Declining reefs may also represent a permanent phase shift to fisher community livelihoods and a loss of cultural heritage. Sewage has been previously implicated in coral reef degradation in Puerto Rico (Goenaga and Boulon 1992; Hernández-Delgado 2000, 2005). In spite of that, there is very limited information regarding the impact of non-point source sewage pollution in benthic community structure

in coral reefs, particularly in highly susceptible species such as Elkhorn coral, *Acropora palmata*.

This study aimed at characterizing the ecological condition of eight shallow-water (<5 m) *A. palmata* assemblages located across a non-point source sewage pollution gradient along the southwestern Puerto Rico shelf. This species constitutes one of the most significant reef-builders in the Atlantic, but their populations have declined by an estimated 97% during recent decades through the region, including Puerto Rico, due to a combination of natural and anthropogenic factors (Hernández-Delgado 2000; Weil et al. 2003). Elkhorn coral was designated in May 2006 as a threatened species under Endangered Species Act 4d rule.

Materials and methods

Studies were conducted at eight coral reefs located along a non-point source sewage pollution gradient across the southwestern Puerto Rico shelf (Fig. 1). Sampling was limited to shallow reef assemblages (<5 m).

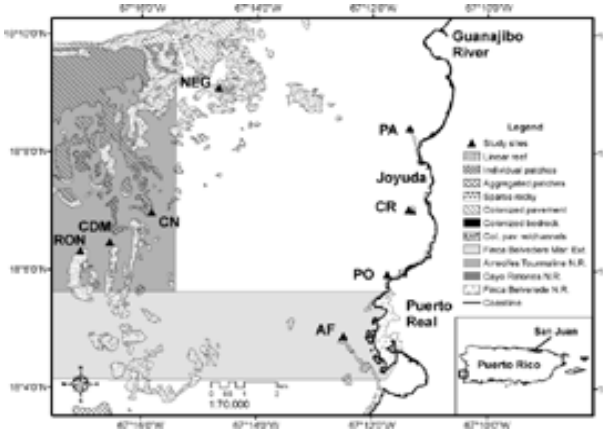

Figure 1. Coral reef study sites: Arrecife Fanduco (AF), Punta Ostiones (PO), Cayo Ratones (CR), Punta Arenas (PA), Arrecife El Ron (RON), Cayo del Medio (CDM), Corona del Norte (CN), and El Negro (NEG).

Sites were arranged into two different geographic regions (inshore, offshore). Inshore reefs (<0.5 km) included AF, PO, CR, and PA (see Fig. 1 for acronyms). Offshore sites (>0.5 km) included RON, CDM, CN, and NEG. Sites were further arranged within two management categories (MPA, non-MPA controls). MPA sites included RON, CDM, CN, CR, and AF. The first three lie within the Tourmaline Natural Reserve. Cayo Ratones is located within the Cayo Ratones and Adjacent Waters Natural Reserve, while Arrecife Fanduco is located within the Finca Belvedere Natural Reserve Marine Extension. These are managed by the PR Department of Natural and Environmental Resources (DNER). Non-MPA control sites included NEG, PO, and PA.

Six replicate 10 m-long linear transects were haphazardously sampled at each site in February 2006. Five replicate non-overlapping 1 m^2 quadrats were haphazardously photographed along each transect using digital photography. Images were corrected for brightness and contrast, and analyzed using CPCE 3.4 software (CPCe, Kohler and Gill 2006), FL. Twenty replicate randomly-generated counting points were projected over each image and used to quantify the proportion of benthic categories. Hard coral (scleractinian + hydrocoral) data was also used to calculate coral species diversity index (H'n) and evenness (J'n).

Community parameter data were analyzed by means of one-way analysis of variance (ANOVA) to test the null hypotheses of no significant site, geographic location, and management regime effects in coral reef benthic community parameters. Significant differences were identified using Tukey's test for comparisons of means. Relationships between benthic community parameter data and data about water microbiological and physical quality obtained from Bonkosky et al. (2008) were analyzed by means of a Pearson correlation analysis. Data on coral species richness and colony abundance were √-transformed, and data on the proportion of % benthic components cover were *arcsin*-√-transformed to reduce variance (Zar 1984).

Community matrices were analysed in PRIMER 6.0 (Clarke and Warwick 2001). Hierarchical clustering usin the Bray-Curtis similarity and group average linkage method (Bray and Curtis 1957) as well as non-metric multidimensional scaling (MDS) and principal components analysis (PCA) were used. Spatial variation was tested using one-way ANOSIM (analysis of similarities). Interaction effects were tested using a two-way crossed ANOSIM. Key taxa responsible for spatial variation were determined using SIMPER and PCA.

Results

Site effects

Mean coral species richness per transect was significantly higher (p=0.0035) at CN (Table 1; Fig. 2). Significantly lower coral species richness occurred at reefs subjected to hurricane disturbance and macroalgal overgrowth due to Guanajibo River influences (i.e., RON), and at inshore reefs subjected to frequent pulses of non-point source pollution. Colony abundance showed a highly significant (p<0.0001) gradient that followed non-point source pollution influences, with a mean higher abundance at offshore sites (Fig. 2). Percent hard coral cover and % *A. palmata* also followed a similarly significant trend (p=0.0004; p<0.0001) (Fig. 3). Percent cover of threatened Elkhorn

coral, *A. palmata*, followed a similar trend with a highly significant (p<0.0001) abundance at offshore remote sites. Living elkhorn corals were completely absent from PA, PO, and AF. These locations were subjected to chronic pulses of non-point pollution and high turbidity.

Table 1. Summary results of one-way ANOVA analysis of coral reef community parameters among sites (d.f.= 7, 33), between geographic locations (d.f.= 1, 39), and between management regimes (d.f.= 1, 39). NS= not significant

Parameter	Sites p	Loc. p	Management p
Species richness	0.0035	NS	NS
Colony abundance	<0.0001	<0.0001	NS
% Coral	0.0004	0.0001	NS
% *A. palmata*	<0.0001	0.0001	0.0462
H'n	NS	NS	NS
J'n	NS	NS	NS
% Octocoral	<0.0001	0.0012	NS
% Sponges	0.0123	0.0012	NS
% Zoanthids	<0.0001	NS	0.0475
% Macroalgae	<0.0001	<0.0001	NS
% CCA	<0.0001	<0.0001	NS
% Cyanobacteria	<0.0001	NS	<0.0001
% SPR	0.0003	0.0194	NS

Percent octocoral cover resulted significantly higher (p<0.0001) at AF and PO, and significantly lower at CDM and NEG. There was a major difference in species composition among sites, with *Pseudopterogorgia* spp., and *Plexaura* spp. being dominant at inshore polluted sites, and *Gorgonia* spp. being more abundant at offshore sites. Sponges were significantly (p=0.0123) more abundant at CDM. Zoanthid *Palythoa caribbaeorum* showed a wide geographic distribution, but at low benthic dominance. *Zoanthus sociatus* was significantly dominant at PA (p<0.0001).

Percent macroalgal cover showed a highly significant (p<0.0001) % cover under turbid and hypertrophic conditions at CR and PO (Fig. 4). Offshore reefs exhibited moderate abundance of macroalgae possibly as a combination of occasional

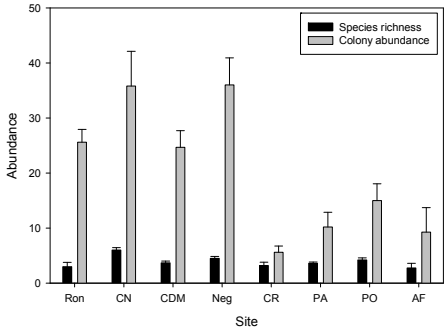

Figure 2. Hard coral species richness and colony abundance.

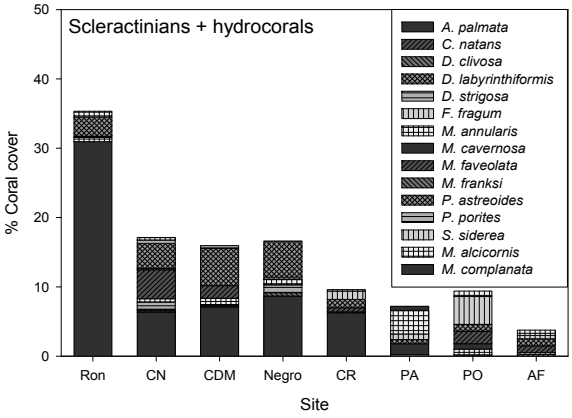

Figure 3. Percent scleractinian and hydrocoral cover.

pulse impacts by Guanajibo River plume and overfishing that has partially depleted large herbivore fish guilds (Hernández-Delgado, pers. obs.). Percent CCA cover was significantly higher (p<0.0001) at offshore remote sites. Mean lower CCA values coincided with dominance by macroalgae and other non reef-building taxa and were observed at inshore polluted sites. Percent cyanobacterial cover resulted significantly higher (p<0.0001) at NEG (Fig. 4), suggesting potential eutrophication pulses associated to the Guanajibo River plume and tidal flushing from polluted Mayagüez Bay. Recently dead corals (RDC) consistently accounted for 3-4% of benthic percent cover of non-living categories at offshore sites, and fluctuated from 1 to 5% at inshore reefs. RDC were largely attributed to the 2005 Caribbean-wide mass coral bleaching event that was followed by extensive coral mortalities until at least mid-summer of 2006 (Hernández-Delgado et al., unpub. data). About 50% of the sampled sites still showed bleached coral colonies at the moment of sampling, including AF (6%), CN (8%), CR (15%), and PO (17%). Further, 5% of the coral colonies at PO and AF were infected by white plague-like disease/syndrome conditions similar to the one that caused massive mortalities across the northeastern Caribbean reefs.

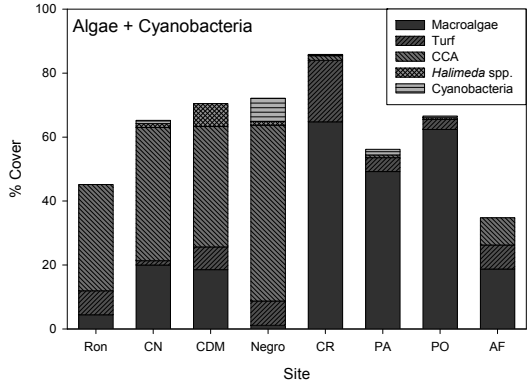

Figure 4: Percent algal and cyanobacterial cover.

Spatial patterns among sites

Two basic clustering patterns of the benthic community structure emerged from MDS analysis at the 50% community similarity cutoff level between inshore and offshore sites (Fig. 5). Four clusters emerged at the 60% cutoff level. Such patterns resulted from macroalgal, octocoral and zoanthid dominance at inshore reefs, and from coral and CCA dominance at the offshore reefs. Spatial patterns of benthic community structure were significantly different among sites (p=0.0002) (Table 2). CCA explained most of the spatial variation among sites (28.6%), closely followed by macroalgae (25%). *A. palmata* explained 14.3% of the variation,

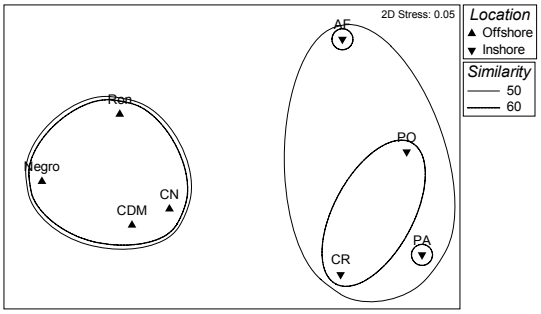

Figure. 5. MDS analysis of the community structure of shallow-water coral reef benthic communities among sites.

while *Pseudopterogorgia* spp. and *Zoanthus sociatus* explained 10.7% of the variation, each one. Spatial patterns were further suggested through PCA analysis, with *A. palmata* and CCA explaining most of the variation at offshore sites. Macroalgae and *Zoanthus sociatus* explained most of the variation at inshore sites, while *Pseudopterogorgia* spp. explained most of the variation at AF.

Spatial patterns between geographic locations

Offshore coral reefs showed significantly higher coral colony abundance (p<0.0001), % coral cover (p=0.0001), and % cover of *A. palmata* (p=0.0001)

Table 2. Results of ANOSIM test for significant differences of coral reef epibenthic community structure. Data was √x-transformed. Based on 5,000 permutations. NS= not significant.

Parameter	Global R	*P* value
One way ANOSIM		
Site	0.725	0.0002
Geographic location	0.875	0.0269
Management regime	0.052	0.3710 NS
Two way crossed ANOSIM		
Site x Location	0.512	0.0012
Site x Management	0.480	0.3333 NS
Location x Management	0.097	0.1300 NS

(Table 2). Also, sponges (p=0.0012), CCA (p<0.0001) and Sand/Pavement/Rubble (SPR) (p=0.0194) were significantly higher in offshore reefs. Octocorals (p=0.0012) and macroalgae (p<0.0001) were significantly higher at pooled inshore locations. Coral reef benthic community structure was significantly different (p=0.0269) between geographic locations (Table 2). CCA explained 14.3% of the variation between locations, followed by macroalgae (10.9%), *A. palmata* (7.5%), *Pseudopterogorgia* spp. (6%), and *Plexaura* spp. (4%). There was a significant site x location interaction (p=0.0012).

Spatial patterns between management regimes

Most parameters showed no significant differences between MPAs and non-MPA sites (Table 2). One exception was % cover in *Acropora palmata* that showed significantly higher % cover within MPA sites (p=0.0462), particularly, within Tourmaline Natural Reserve. Percent zoanthid cover (p=0.0475) and % cyanobacteria (p<0.0001) resulted higher within non-MPA control sites. Coral reef benthic community structure showed no significant difference between management regimes (Table 2). CCA explained 11.2% of the variation in benthic community structure between management regimes, followed by macroalgae (9%), *A. palmata* (8.6%), *Pseudopterogorgia* spp. (6%), and *Zoanthus sociatus* (4%). These results revealed that impacts of non-point source pollution have not discriminated between management regimes, further implying that pollution pulses can potentially affect widespread geographic areas and that current management measures have had no impact on water quality.

Relationship of coral reef community parameters and non-point source fecal pollution

A Pearson correlation analysis revealed several significant correlation patterns with microbial parameters obtained from a simultaneous study by Bonkosky et al. (2008). Zoanthids and cyanobacteria (r>0.95, p<0.01) were strongly correlated with enterococci counts, suggesting their dominance under hypertrophic, fecal-polluted conditions. Macroalgal cover was significantly correlated (r=0.94, p<0.02) to the frequency of *Bacteroides* GB32 molecular marker. *Bacteroides* is an anaerobic microorganism that grows in human and other warm-blooded animals gut. Therefore, its presence in environmental samples reveals a recent fecal pollution event. Macroalgae showed a marginally significant relationship (r=0.87, p=0.053) with *Bacteroides* molecular marker HF183. This probe is specific for human-derived fecal pollution. This suggests that inshore coral reefs were

subjected to non-point source sewage pollution, mostly from human sources.

Discussion

There is unequivocal evidence that coral reefs along a significant portion of the southwestern Puerto Rico shelf are being significantly impacted by non-point source sewage pollution, mostly from human origin (Bonkosky et al. 2008). The historical combined and cumulative impact of natural factors (i.e., hurricanes), with long-term pollution pulses, and other potential anthropogenic reef degrading factors, such as sedimentation pulses and overfishing, have contributed to a dramatic phase shift in coral reef community structure. They have favored dominance by macroalgae and non reef-building taxa. Current MPA management activities have had no significant impact on the status of coral reef benthic communities. The spatial extent of non-point source sewage pollution can be frequently underestimated due to failure to detect fecal pollution or due to the lack of water quality monitoring. But recurrent pulses can be a major long-term threat to coral reefs in face of climate change and need to be addressed.

Conclusions

Most inshore coral reefs along the southwestern Puerto Rico shelf have significantly degraded at such a magnitude that recovery may never occur in a human time scale. Stronger efforts are needed to prevent further degradation of remote reefs through the region. There is an immediate need to implement a sound management strategy to reduce and/or prevent non-point source sewage pollution impacts in coral reefs before we witness an ecological and socio-economic collapse. Controlling and managing pollution will require a definite strong political will and commitment in the government of Puerto Rico aimed at establishing stringent controls over land use patterns and over land-based pollution. Failing to recognize and manage non-point source sewage pollution may result in further loss of remote reef systems along the Puerto Rico shelf that are already showing the early signs of degradation.

Abstract. In July 2006, the Academy of Natural Sciences of Philadelphia organized an expedition to New Providence Island, Bahamas. Coral species richness and cover, and reef surface rugosity were examined at Delaport Point (DP), Green Cay (GC), and Long Cay (LC). Greatest number of coral species (27) was observed at DP2 and the fewest (14) at DP3. Rugosity was greatest at GC1 due to the spatial complexity of an *Acropora palmata* reef. Coral cover tracked well with rugosity index (RI); GC1 with an average RI of 1.7 had coral cover (20.56%) superior to the other stations. Algae were the most abundant benthic cover component: mean= 50.99 ± 25.45% (SD); stony coral cover ranged from 0.65 to 20.56%, and the mean was 6.72 ± 6.94%. Bray Curtis similarity was greatest among GC stations and transects. ANOSIM two-way test documented that replicate transects at sampling stations were not different (Global R =0.066); however, site locations were different (Global R = -0.259). SIMPER analysis showed that macro algae genera *Dictyota, Lobophora,* and *Stypopodium* were responsible for differences in the station assemblages. Taxonomic Distinctness and Variation in Taxonomic Distinctness evaluations reported that Distinctness is stable but high Taxonomic Variation may indicate community instability.

Key words: New Providence Island, Bahamas; Community structure; Taxonomic distinctness; Rugosity

Introduction

The Bahamas archipelago (260,000 km^2) extends 800 km from SE Florida to northern Hispaniola (Gerace 1988). The majority of The Bahamas is located on two shallow banks, ideal for coral reef development. Land (islands and shoals extending above the highest tides) occupies 11,400 km^2 (4.4% of the Bahamas area). The islands are low with few cases of greater than 30 m elevation. New Providence Island is situated on an east-west axis between Andros Island to the west and Eleuthra Island to the east; the islands are situated on the Great Bahamas Bank.

Engelhard (1915) reported that, of the reefs around New Providence Island, the best coral reef development was at Sandy Cay, due north of the eastern point and Goulding Cay, west of the western point of the island. Goulding Cay was the site of a multi-year coral growth-rate study (Vaughan 1915). From the east end of New Providence a chain of reefs extends to Eleuthera; reefs were also prolific in the region north of Spanish Wells (Haweis 1917; Miner 1924, 1931, 1933). Haweis published a fascinating small book about the coral reefs of Nassau, calling them "sea gardens." He noted that there were five shallow habitats (types of ocean bottom) around the Bahamas: "soft sand; flat, sandy coral rock; coral reef; feather bar; and grass." In those days, visitors could board a glass bottom motor launch at the Colonial Hotel to have a look at the reefs (Haweis 1917).

In July 2006, the Academy of Natural Sciences of Philadelphia organized an expedition to study historical sampling locations based on the Böhlke and Chaplin (1968) field notes obtained from the Academy and the personal recollection of Gordon Chaplin who participated in the original studies (Chaplin 2006). We examined coral reef habitat (coral species diversity, coral cover, and rugosity of the reefs) in conjunction with Kellogg's reef fish studies (in progress).

Material and Methods

Each site (Delaport Point [DP], Green Cay [GC], Long Cay [LC]) included three sampling stations stratified by depth (1: 1.5 to 6.1m; 2: 6.2 to 7.6m; 3: 7.7 to 15.2 m). Three 25m long transects were established at each station (Table 1).

We sampled stony coral species richness with a 20 minute long visual survey. A five mega-pixel digital camera in an underwater housing with a reference rod that positioned the camera 40 cm from the reef surface was used to capture benthic cover (N=40 images per transect); image size was approximately 0.16 m^2. Forty images provide a planar area of 6.4 m^2 per transect and 19.2 m^2 per sampling station. Benthic cover was analyzed using point count analysis (Jaap

and McField 2001; Kohler and Gill 2006). Rugosity was measured with a chain along a ten m long path at each transect (Dahl 1973).

Sites:	Green Cay (GC)	Long Cay (LC)	Delaport Point (DP)
Station 1	25°06.283'N 77°11.822'W	25°05.576'N 77°23.899'W	25°04.786'N 77°26.631'W
Station 2	25°06.292'N 77°11.857'W	25°05.539'N 77°23.253'W	25°04.472'N 77°28.210'W
Station 3	25°06.547'N 77°11.762'W	25°05.705'N 77°23.417'W	25°05.279'N 77°26.306'W

Table 1. Sampling station coordinates.

Multivariate analyses, based on benthic components (species and genera), used Clarke's (1993) non-parametric approach, implemented in the PRIMER-E 6 software (Clarke and Gorley 2006). All point-count values were square-root transformed, so that the multivariate analyses would draw on species from across the whole assemblage rather than being either dominated only by the two or three species with the highest cover or overly influenced by rare species (Clarke and Green 1988). Bray-Curtis similarities were then computed to compare transects and station samples (Bray and Curtis 1957; Bloom 1981). Finally, triangular matrices were input to non-metric multidimensional scaling ordination (MDS) (Kruskal 1964) and ANOSIM test for establishing differences between habitat or location groups (Clarke and Green, 1988; Clarke 1993). The SIMPER procedure (Clarke 1993) was used to identify species most responsible for observed differences in assemblage structure.

TAXDTEST was employed to evaluate the taxonomic distinctness of the species assemblages (Clarke and Warwick 1998; Warwick and Clarke 1998; Warwick and Clarke 2001). The procedure evaluates taxonomic distinctness (TD, Î+) of the sample, compares it to a regional pool of all species and to the variance in taxonomic distinctness (VarTD, Lambda+). The method is robust, and independent of sampling effort (Clarke and Warwick 1998, 2001; Warwick and Clarke 2001). Data were exhibited in a confidence funnel and ellipse graphics. The regional Scleractinia database includes a comprehensive 1975 study at Grand Bahama (Jaap and Olson 2000) and compiled distribution data from Atlantic, Caribbean, and Gulf of Mexico locations; it was used as a comparison with the New Providence data set. The TAXDTEST was also used for regional comparison, including the Gulf of Mexico, eastern Atlantic, Bermuda, Brazil, and Caribbean.

Results

Stony coral species richness was greatest (27) at DP2 (Table 2) and the poorest (14) at DP3. Six species (*Millepora alcicornis, Siderastrea siderea, Porites astreoides, Diploria labyrinthiformis, Diploria strigosa*, and *Montastraea annularis*) occurred at all sites and stations. *Acropora cervicornis, Scolymia lacera, Scolymia cubensis,* and *Mycetophyllia ferox* were only seen at one station.

Site and Station	RI	S	Algal cover	Coral cover
DP1	1.47	16	28.26	2.04
DP2	1.44	27	51.85	11.95
DP3	1.20	14	2.83	0.65
GC1	1.77	18	32.22	20.56
GC2	1.83	18	72.06	6.29
GC3	1.43	22	73.19	12.98
LC1	1.49	15	57.10	2.99
LC2	1.22	19	81.68	1.81
LC3	1.15	21	59.80	1.23

Table 2. Mean Rugosity Index (RI), species richness (S), algal and coral cover (%) for the New Providence stations.

Rugosity was greatest at GC1 and GC2; the complexity of the *Acropora palmata* habitat was a contributing factor at GC1 (Table 2). Stations with RI values exceeding 1.4 had the greater number of stony coral species; however, the station with the highest RI values (GC2) had fewer coral species than several other stations. Coral cover generally matches well with rugosity; GC1 with an average RI of 1.71 had coral cover that was superior to the other stations. The exception occurs at station GC2 with an average RI of 1.83 but relatively low coral cover (Table 2). Spearman rank correlation for coral cover, number of species, rugosity, and taxonomic distinctness documented mediocre correlations.

Macro algae dominated benthic cover (Table 2); however, it was quite variable, ranging from 81.68% at LC2 to 2.83% at DP3. Coral cover (principally dense thickets of *Acropora palmata*) was greatest at GC1. Sponges contributed 4.84 (DP1) to 0.31 (GC3) % cover, octocorals contributed 8.00 (LC1) to 0 (DP1) % cover, and zooanthids provided 0.09 (LC3) to 0 (several stations) %cover.

Benthic community structure characterized by species cover depicts that fidelity is greatest among the GC stations (Fig. 1); GC1 (*Acropora palmata* community) and DP1, expressed the greatest similarity of the sampling transects; DP3 transects had the greatest dissimilarity (Fig. 1).

Analysis of Similarity (ANOSIM) two-way crossed test documented the differences between location and habitat. Replicate transects at sampling stations are similar (Global R=0.066); however, the site locations are different (Global R= -0.259).

Macro algae genera *Dictyota, Lobophora,* and *Stypopodium* were most responsible for differences in the assemblages (SIMPER, one-way test). When the

algae genera were removed from the analysis, coral species and genera were responsible for the dissimilarity. *Acropora palmata* contributed 20 to 30% of dissimilarity, setting GC1 apart from other stations.

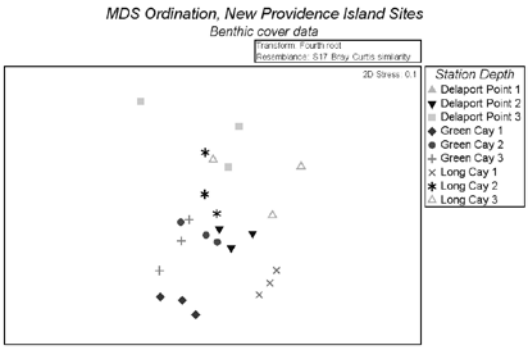

Figure 1. Multi-Dimensional Scaling (MDS) Ordination of Transects, Species Cover Attributes Used as Input for the Bray-Curtis Similarity Analysis.

Taxonomic distinctness (Delta+) values (TAXDTEST) ranged from 59.68 (GC2) to 65.28 (DP1); Lambda+ values range from 283.85 (LC3) to 614.96 (LC1). Taxonomic distinctness has not declined remarkably at these sites (Fig. 2). There is a high degree of variance in taxonomic distinctness at GC1 and LC1, likely because several of the species that occurred there were rare or nonexistent at the other sites.

Discussion

Few pre-1970 studies quantitatively assessed coral diversity and cover in the Bahamas. Photographs in these studies show evidence of coral cover; however, photos often featured the premiere attributes of the sites at that time; it is surmised from this that, typically, coral cover exceeded 30 to 40% in many locations in the Bahamas, especially in areas where *Acropora palmata* predominated.

In a study conducted in 1975 off Freeport, Grand Bahama (Jaap and Olson 2000), coral cover ranged from 1.48 to 30.28%. This was, however, for the most part in depths (30 to 70 m) that exceed the present study.

Chiappone et al. (1997) surveyed reefs in depths of 3 to 15 m along the Exuma Cays (south of New Providence Island) in 1995. Algae cover ranged from 20 to 80%, sponge cover from 10 to 40%, octocoral cover from 2 to 5%, and scleractinian coral cover from 2 to 40%. The survey reported 43 species of sponges, 29 octocoral species, and 39 stony coral species. This current study identified 32 stony coral species (Milleporina and Scleractinia) from the three sites around New Providence Island.

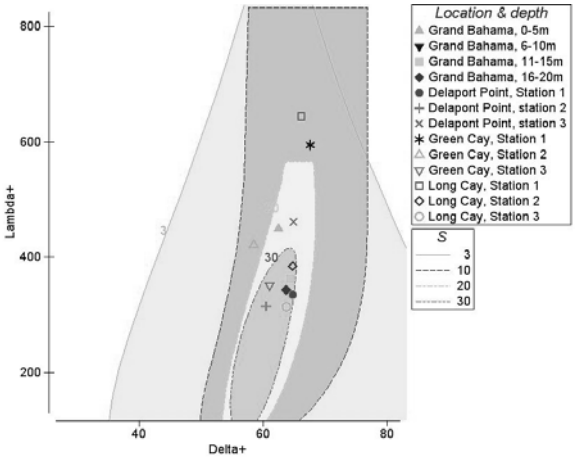

Figure 2. Taxonomic Distinctness (Delta+) and Variation in Taxonomic Distinctness (Lambda+) for the New Providence and Lucaya, Grand Bahama, Sampling Stations.

Zooxanthellate Scleractinia (ZS) distribution and taxonomic distinctiveness for the Gulf of Mexico, Florida, Bahamas, Caribbean, and south Atlantic localities are related to spatial distances: the southeastern and southwestern GMEX regions have a high degree of faunal similarity with SE Florida, the Bahamas, and the Caribbean; however, there is a low similarity with southeastern USA (North of the St. Lucie Inlet to Cape Hatteras), south Atlantic, and the eastern Atlantic (Figs. 3 & 4). Ocean current patterns within the Gulf and Caribbean provide a source of connectivity for Bahamas, Cuba, Florida, and Mexico. The cluster pattern (Fig. 3) is consistent with connectivity in the region and isolation from distant locations.

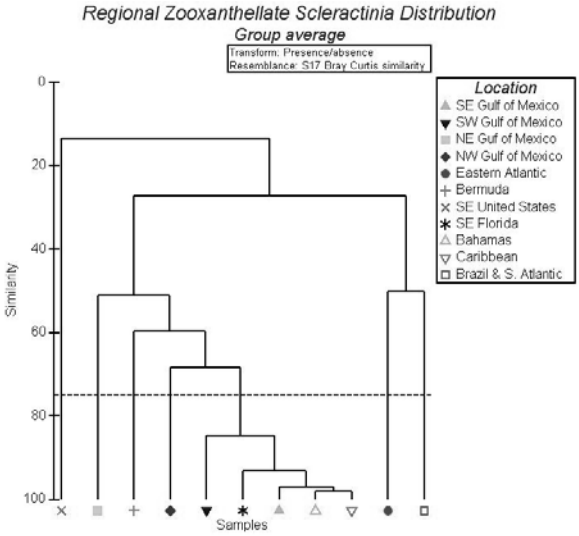

Figure 3. Cluster diagram of the distribution of zooxanthellate Scleractinia in the Atlantic Ocean and Gulf of Mexico; presence or absence of species at these locations. Bray Curtis Similarity coefficient and group average sorting.

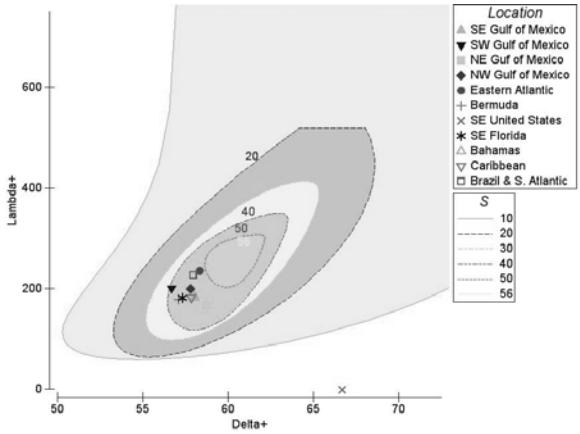

Figure 4. Taxonomic Distinctness (Delta +) and Variation in Taxonomic Distinctness (Lambda+); regional comparison of zooxanthellate Scleractinia.

We interpret the high VarTD to be the result of a reduction in certain habitats that are obligatory for some species at some sites, the abundance and competition by algae for space, and the result of tropical storm disturbances in 2004 and 2005. A comparison of the New Providence Island Site VarTD with regional VarTD (Figs. 2 & 4) shows relatively lower values for VarTD at the regional level. TD distinctness and variation (Fig. 4) in contrast to the cluster analysis (Fig. 3) shows that the zooxanthellate Scleractinia do not exhibit a large range of Delta+ and Lambda+ in the remote locations, such as Brazil, Azores, and Bermuda. This is due in part to very few endemic species and to the wide distribution of many species in the region.

Decline in coral reefs around New Providence Island may be caused by runoff and groundwater seepage from the surrounding highly populated areas. Runoff carries nutrients, metals, pesticides, chemicals, and biocides, all of which are detrimental to the vitality of the coral reef communities. We noted that there are virtually no attached organisms at DP1 and DP3 sites, which are in close proximity to densely populated urban areas and are situated near a channel facilitating transport from the shoreline. Green Cay sites are located a moderate distance from the urban developments on New Providence, and the typical epibenthic reef flora and fauna are common.

Nutrient enrichment often results in increases in macroalgal growth, particularly in areas near coastal development and increased sewage outflow (Smith et al. 1981; Birkeland 1988; Pastorak and Bilyard 1985). Macro algae were the most prevalent biotic cover component at all nine of the sampling stations. We also suspect that the large algae population is related to a decrease in herbivores (e.g., fish and *Diadema antillarum*).

Comparisons of reefs in Montagu Bay (New Providence Island) with 1943 aerial photos documents that startling declines in stony coral cover have occurred over the last half century (Sullivan Sealey 2004). Patch reefs in the bay decreased from 214 to 133 in 52 years. Aerial photographs also indicate that many coastal construction projects were undertaken between 1943 and 1995, significantly altering the coastline and, most likely, increasing the physical destruction of reefs through increased sedimentation and turbidity. Bahamian reefs were recently listed as over 60% degraded, trailing Jamaican and Panamanian reefs in total loss (Pandolfi et al. 2003). The Bahamas have made a commitment to conserve 20% of their coral reef ecosystems in the form of no-take areas or marine protected areas (Pandolfi et al. 2003), although no timeline has been directly specified. No-take reserves and marine protected areas have been shown to be effective mitigation and replenishment measures, and it is important that they are established in heavily populated areas such as New Providence Island, where unsustainable development has already led to significant declines in fish, corals, and other benthic invertebrates. These measures are limited, however, in their ability to combat the effects of degraded water quality. The Bahamian government needs to implement a new sewage treatment system. Continued degradation of water quality will occur unless significant improvements are made in the infrastructure.

Status of reefs in the Bahamas is far better in remote areas such as Cay Sal Bank than in highly urbanized islands such as New Providence. Reef degradation around New Providence is mostly the result of urban development pressures in the coastal zone. Status and trends of mangroves, sea grasses, and coral reefs in the Bahamas is similar to other Caribbean countries where coastal resources have been used as a tourist attraction for economic stimulus. This, coupled with radical declines in *Acropora* reefs (the causes of which are enigmatic), has resulted in coral reefs that are degraded and covered with algae. Monitoring programs can determine the status and future trends of resources; however, they can only serve as an ecological warning system. Basic research, management, conservation, and social action are required to resolve the problems, be they local, regional, or global.

Acknowledgement

Support for the study was provided by The Academy of Natural Sciences of Philadelphia. Special permits were approved by the Government of the Bahamas, Department of Marine Resources. They also provided the R/V *Guanahani*, captain, crew, a small boat, and a high pressure air compressor to refill diving cylinders.

Comparison of Benthic Communities on Six Coral Reefs in the Veracruz Reef System (Mexico)

J. Jones, K. Withers, J.W. Tunnell Jr.

Texas A&M University-Corpus Christi, 6300 Ocean Dr., Corpus Christi, Texas, USA

Abstract. The Veracruz Reef System consists of 25 platform reefs that are split into two subgroups, northern and southern, by the influence of the Río Jamapa. Scleractinian coral cover on all reefs has declined dramatically since the 1960s. Using historical data and regression analysis, we predicted ~15% cover for the northern subgroup and no coral cover in the southern subgroup. Anegada de Adentro and Blanquilla, in the northern group, and Anegada de Afuera, Cabezo, Enmedio, and Santiaguillo, in the southern group, were surveyed during Fall 2002 with photo-transect techniques. Scleractinian cover averaged 3.2% in the northern subgroup and 6.3% in the southern. Algae, particularly turf and crustose forms, dominated reef benthic communities, with greater than 50% cover on all reefs and at all depths. Coral cover was much less than predicted in the northern subgroup and was greater than predicted in the southern subgroup. Numerous natural impacts (low salinity, heavy sedimentation, diseases, winter cold fronts, hurricanes) and anthropogenic impacts (coral mining, dredging, landfill, ship groundings overfishing, coral and shell collection, others) have undoubtedly caused much of this decline. In the southern group, declines appear to have leveled off while becoming more severe in the northern group.

Key Words: coral decline, Veracruz Reef System, southwestern Gulf of Mexico

Introduction

The coral reefs of the southwestern Gulf of Mexico lie along the western boundary of the Caribbean Biotic Province (Tropical Western Atlantic Region) (Briggs 1974, Tunnell 1988). The highly endangered Veracruz Reef System (VRS) (Bryant et al. 1998) located off the state of Veracruz, Mexico (Fig. 1) consists of 25 platform-type coral reefs. These reefs are divided into two subgoups by the influence of the Río Jamapa: the northern near the city of Veracruz and the southern near Antón Lizardo, a small fishing village. Compared to other reefs within this biotic realm, these reefs have lower stony coral diversity, primarily due to frequent climatological events and turbidity from coastal runoff. Southwestern Gulf of Mexico corals occur at the limits of their distribution limiting reef biodiversity thus anthropogenic stressors have profound effects on the ecosystem (Tunnell 1988, Nelson 1991). The combination of both natural and anthropogenic disturbances exacerbates reef impacts and reduces coral cover.

Historically, live benthic coral cover on reefs in this area has been less than 40% and on nearly all reefs coral cover has declined in recent years (Lang et al. 1998). Most of these reefs have been greatly affected by overharvesting, pollution, and recreational diving; the amount of stress and destruction depends on their proximity to urbanized areas (Tunnell 1985, 1988, 1992, Chávez and Tunnell 1993). Due to the city of Veracruz's large size and reef geographic location, the VRS has suffered the heaviest anthropogenic impacts of any reefs in Mexico (Bryant et al. 1998, Jordán-Dahlgren and Rodríguez-Martínez 2003). Coral cover has declined since the 1960's and algal cover has increased.

Figure 1: Reefs of the Veracruz Reef System, in the southwestern Gulf of Mexico, near Veracruz and Antón Lizardo, Mexico. Modified from Tunnell (2006).

The goal of this research was to assess the condition of six reefs in the VRS: Anegada de Adentro and Blanquilla in the northern subgroup and

Anegada de Afuera, Enmedio, Santiaguillo, and Cabezo in the southern subgroup. Cover of scleractinian corals on reefs in the VRS has declined by more than 60% since the 1960's (Horta-Puga and Barba-Santos 1999). Based on regressions of historic coral cover data (Kühlmann 1975, Rannefeld 1972, Secretaría de Marina 1987, Nelson, 1991, Horta-Puga 2003), we predicted ~15% cover for the northern subgroup in 2002 and no coral cover for the southern subgroup (Fig. 2).

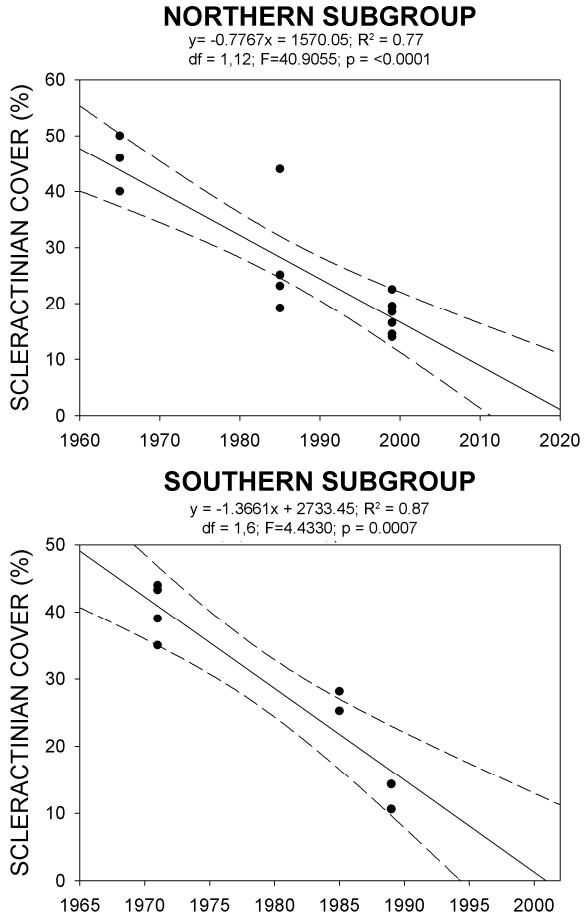

Figure 2: Trends in scleractinian coral cover in the northern and southern reef subgroups of the Veracruz Reef System, Mexico.

Methods

Each of the six reefs was surveyed using photographic techniques (Liddell and Ohlhorst 1987) at 6m, 12m, 18m, and when depth permitted, 30m. Six transects, each consisting of 12 non-overlapping photos, were completed at each depth although not all transects produced usable images. Photographs were processed to produce digital images. Each photo was projected and overlain with 144 points arranged in a uniform pattern. The coral taxon or benthic category (e.g., crustose algae, bare etc.) under each point was determined and recorded. Percent cover of scleractinian corals, algae and bare areas were calculated for each transect and averaged by reef and depth.

Results

Algae dominated benthic communities of all reefs and at all depths (Fig. 3). In the northern subgroup, coral cover averaged 3.2% and algal cover averaged 69.4%. Although very low, coral cover varied substantially with depth ranging from 1% or less at 6m and 18m on Blanquilla to the maximum of 6% at 12m. On Adegada de Adentro, maximum coral cover was also found at 12m (8%) and ranged from 0.5% at 6 m to 4% at 18m. Algal cover was greatest at 6 m on both reefs, and varied slightly with depth ranging from 58-76% on Blanquilla and 66-80% on Adentro.

In the southern subgroup, coral cover averaged 6.3% and algal cover averaged 66.2%. Average coral cover was higher in this subgroup largely due to greater cover at Santiaguillo, which ranged from 9% at 30m to 18% at 18m. Maximum coral cover on the other reefs was similar to that seen in the northern subgroup: 6% at Enmedio (12m) and Cabezo (18m), and 7% at Anedgada de Afuera (30m). Algal cover was least at Santiaguillo (50-57%) and ranged from lows of ~65% at Afuera (30m) and Cabezo (18m) to a high of 78% at Cabezo (6m).

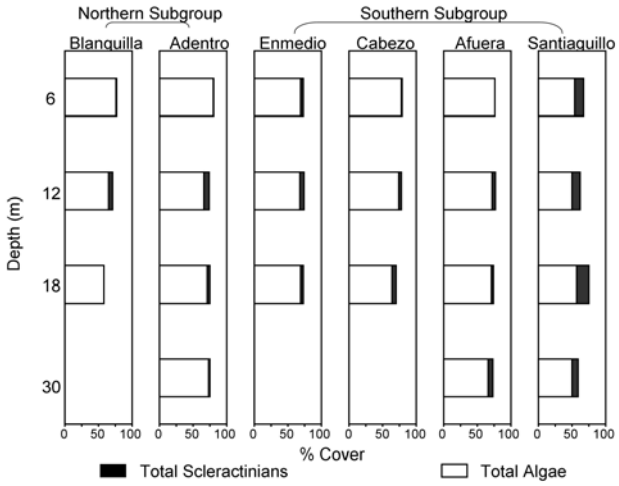

Figure 3: Average scleractinian and algal cover by depth in reefs surveyed the northern and southern subgroups of the Veracruz Reef System, Mexico. There were no 30m transects surveyed at Blanquilla, Enmedio or Cabezo.

Coral communities on the reefs surveyed were typically dominated by six species or species complexes (Table 1): *Montastraea annularis* complex, *Diploria strigosa*, *Colpophyllia natans*, *Siderastrea siderea*, *Agaricia* spp. (especially *A. lamarcki*) and *M. cavernosa*. In the northern

subgroup, 11 scleractinian species were noted at Blanquilla with 14 species at Anegada de Adentro. In the southern subgroup, the most scleractinian species (16) were noted at Santiaguillo and the least at Cabezo (10). Live colonies of *Acropora palmata* were found on Enmedio as well as Anedgada de Adentro and Santiaguillo, although they were very rare on the latter two reefs.

Discussion

Coral cover and diversity in the Veracruz Reef System is naturally limited by weather, especially winter cold fronts ("nortes"), turbidity from coastal runoff, (Horta-Puga 2006, Chávez and Tunnell 2006) and their location on the tropical periphery (Withers and Tunnell 2006). Poor management and deteriorating water quality from pollution and deforestation affect the whole region, where only the most isolated reefs are generally healthy (Linton et al, 2002, Horta-Puga 2006). Multiple anthropogenic impacts, especially around large cities, have lead to declines or total losses of stony corals. As coral cover

has declined, crustose and fleshy algae have increased as space is freed up for them to colonize (Aronson and Precht 2001). The combination of the *Diadema antillarum* die-off in the 1980's and increased overfishing of herbivorous fishes (Lang et al. 1998, Tunnell et al. 2006), both of which controlled algal growth on reefs, has allowed algae to colonize the open spaces.

In this study, coral cover in the northern subgroup was less than the ~15% predicted mean and cover in the southern subgroup exceeded the mean prediction of no cover remaining. Greater average cover in the southern subgroup was primarily due to the influence of Santiaguillo, the reef furthest from shore. However, even when this reef is excluded, average cover for the southern subgroup, 4.1%, is substantially greater than predicted mean and exceeds the average in the northern subgroup.

Scleractinian coral cover has declined dramatically in both reef subgroups since the 1960's, when it averaged 40-50% overall (Kühlmann 1975; Rannefeld, 1972; Secretaría de Marina, 1987; Nelson, 1991; Horta-Puga, 2003). However, the decline to less than the predicted mean and lower 95% confidence interval cover in the northern subgroup shows that conditions deteriorated rapidly between 1999 (Horta-Puga, 2003) and 2002 (this study). On the other hand, coral cover in the southern subgroup exceeded the mean predicted, although it fell within the 95% confidence interval. This suggests that conditions causing the decline have stabilized or begun to be reversed in this area.

A photographic method for analyzing areal chlorophyll and bleaching status of the coral *Stylophora pistillata*

S. Koren[1], Z. Dubinsky[1], O. Chomsky[1]

1) The Mina & Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Israel.

Abstract. With the increasing frequency and severity of coral bleaching events, this phenomenon has been documented and studied by scientists around the world. Methods to quantify bleaching status are based on sacrificing the samples being tested or using expensive equipment (like the diving PAM). In recent years, the performance of digital cameras in image processing has improved and they have become more affordable, thus, we used these to develop a new, economical and nondestructive way to monitor bleaching and recovery processes in coral tissues, to be used by conservationists and researchers. In the present study, we report a reliable bioassay for computerized quantification of areal chlorophyll density in corals. We used a regular digital camera and standard computer software, both inexpensive and easily available. The proposed bioassay could be used on any coral to rapidly and economically gather data on coral bleaching and disseminate them.

Key words: Coral, Bleaching, photography, chlorophyll.

Introduction

Corals and their colors

Corals and coral reef ecosystems depend on the unique symbiosis between the host animal, the coral, and single-cell algae, the zooxanthellae (Brandt 1881). These live within the coral cells, in specialized vacuoles, the symbiosomes (Trench 1971, 1974; Gates 1992).

Besides some effect of the animal's water-soluble pigments (Shibata 1969), the color of corals depends primarily on the areal concentration of the photosynthetic pigments of the zooxanthellae. Thus, it reflects the product of the density of the symbionts and their cellular pigment content, with chlorophylls being the most prominent.

Coral bleaching

In well-publicized bleaching events, corals have turned white, usually due to loss of zooxanthellae (Glynn 1996), but occasionally as the result of a decrease in algal pigmentation (paling). These bleaching episodes are triggered by a sustained increase of water temperature, occasionally acting synergistically with high light, UV radiation, eutrophication, and disease (Glynn 1990, 1993; Dubinsky & Stambler, 1996), and result in widespread colony mortality and reef destruction.

The documentation of bleaching

In order to document and monitor bleaching events around in real time, it is of great importance and urgency to develop reproducible, rapid, reliable, inexpensive, and nondestructive ways to quantify coral pigmentation. Much of the early and current reporting of bleaching events is based on diver information and qualitative descriptions (Wilkinson and Buddemeier 1994). These are insufficient and there is a need for quantifiable methods for revealing the onset of bleaching in corals, and document instances in which recovery takes place.

Past attempts to achieve this goal were difficult and tedious. Thieberger et al. (1995) used 35 mm color slides taken under standard conditions, which were then scanned in a specially designed adapter in a spectrophotometer. Several subsequent efforts at different spatial scales and resolutions were tried in order to document the status of entire reefs, usually based on expensive, custom-made, hyperspectral scanners (Elvidge 2003). However, these were inadequate for determining the advent of bleaching on a single-colony level. The use of a digital camera to determine bleaching status in corals using a color reference card has been reported recently (Siebeck at al 2006) however the present method is more convenient and precise.

Most reefs are found in remote areas and in developing countries, far from well-equipped, academic research centers. Therefore, what is needed is a means to monitor coral-bleaching events and their aftermath using straightforward, standardized procedures. Ideally, such a system – based on off-the-shelf digital underwater cameras – should be designed to be used rapidly and economically by field technicians and reserve operating personnel at hundreds of locations. The resulting digital information can then be easily communicated worldwide.

Materials and Methods

Coral fragments

Three colonies of *Stylophora pistillata* were gathered from the reef near the Interuniversity Institute, Eilat, Israel, in the Gulf of Eilat (Aqaba). Corals of 15-cm diameter were collected from artificial objects at a depth of 2.5-3.5 m. The corals were allowed to acclimate for one month in our main aquarium system under 500µ mole quanta m^{-2}. Then the corals were divided into 3-cm-long fragments and glued with Super Glue Gel (Scotch, 3M) to plastic tips (Fig. 1).

Figure 1: *Stylophora pistillata* fragments during acclimation in our main aquarium system

The Fragments had divided between controls remaining in the light and the bleaching ones in the dark for 44 days. Every two weeks 3 fragments were photographed and extracted, and from these data the calibration curve (Fig. 4) and figure 5 were obtained.

Digital photographs

Coral fragments were taken from the aquaria in a seawater-filled beaker, photographed, and immediately returned to the water to minimize air exposure, or they were processed for analyses as described below.

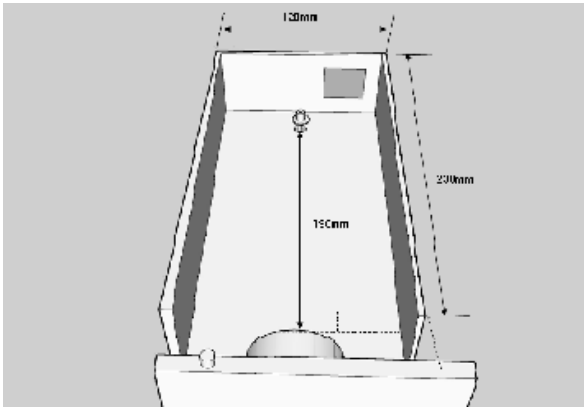

Figure 2: Camera stand sketch. The coral fragment was placed in the center of the image at 190 mm from the camera lens, with the gray plate at its right.

Digital images were taken with an Olympus 750 camera with 4 M pixel resolution. To be able to compare images, camera-to-coral distance, illumination, and state of extension of the polyp tentacles were kept constant. A gray 30□40-mm PVC plate was included as a reference (red=200, green=200, and blue=200 as a standard color reference card, see below for details) (Fig. 2) in each photograph.

We used a plastic stand to position the fragments and camera at a fixed distance and angle (Fig. 2), to the right side of the fragment position we attached the PVC plate. The distance between the camera lens and the fragment's nearest surface was 190 mm and the fragment was orientated to be at the center of the image. All the photographs were taken using the camera's internal flash. To keep the polyp tentacles fully retracted, we photographed the fragments out of the water. For an in-water procedure, one can disturb the water near the coral (by hand or pump) and cause the tentacles to retract. The gray PVC sheet was attached at the same distance from the camera as the fragment, in order to eliminate any differences in lighting since we regard its color as the standard for calculations. All pictures were taken with a shutter speed of 1/60s and aperture of f=1.8.

Picture analysis

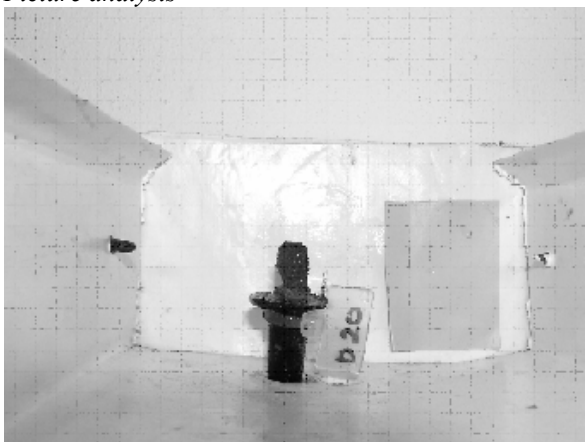

Figure 3: *A sample of the image taken by the camera. The coral fragment is in on the plastic stand with the grey reference plate to its right*.

Analysis of the digital images (Fig. 3) was done using Paint Shop Pro (Corel Corporation, Ottawa, Ontario, Canada). All images were cropped to a square of 100*100 pixels, covering an area of 7.5 by 7.5 mm live coral tissue. Likewise, 100*100 pixels of the gray sheet image were cut from the picture. For each such square, a wavelength histogram graph (including only the green channel) was produced by the appropriate Paint Shop option, and the average value of the 10,000 pixels (100*100) was calculated. This value was found to be between 0 for black and 255 for white paper.

The sample size was chosen as to include the largest possible homogenous fragment area. In the branched *Stylophora pistillata*, the average width of

the subcylindrical branches was found to be ~10 mm. The chosen size allowed us to photograph a nearly flat surface perpendicular to the camera lens. In preliminary experiments, we found that correlation improved as we increased the sample area to the maximum of 7.5 mm square.

For standardizing images and results, all readings were corrected for the gray standard as seen in Eq. 1. In this way, the lighter the coral is, the higher the resulting value.

Eq. 1 P = 255 - [Gray sheet average] + [Coral tissue average]

Thus, low P values correspond to a darker image and higher chlorophyll concentrations, the P value ranged between 100 (high) to 250 (low).

Pigment extraction and quantification

In order to calibrate the data obtained from the photographs, we used the standard methods for quantifying chlorophyll in *S. pistillata* and other corals (Dubinsky et al. 1990; Titlyanov et al. 2000; Nordemar et al. 2003). The procedure requires sacrificing the sample using the Water-Pik method (Joahnnes and Wiebe 1970; Falkowski and Dubinsky 1981; Hoegh-Guldberg and Smith 1989; Edmunds and Gates 2002) to remove the animal tissue with the zooxanthellae from the skeleton. The resulting homogenate was filtered through a 25-mm Ø glass fiber paper filter (Whatman GFC). The zooxanthellae collected on the filter were extracted in 10 ml 90% acetone/water by grinding the filter with a glass/PTF homogenizer. The resulting slurry was filtered again through the same type filter. Chlorophyll concentration was quantified spectrophotometrically with a Varian DMS 100S, according to the Jeffrey and Humprey (1975) equations from the ODs 665nm and 755nm, and normalized to sample area.

Fragment area was determined using the aluminum foil method (Falkowski and Dubinsky 1981; Hoegh-Guldberg and Smith 1989; Edmunds and Gates 2002).

Results & Discussion

Comparison the extracted chlorophyll measurements and our estimates based on analysis of the photographs of the same fragments, resulted in a logarithmic trend line (Fig. 4, Eq. 2)

Eq. 2 y = -11.41n(x) + 62.274, R2= 0.919

This proves that estimating areal chlorophyll density can be done by photographing and analyzing a digital image of a coral fragment or colony. The S. pistillata control fragments had a concentration of 7.2±0.9 chlorophyll a mg cm-2 as determined by the standard method, and 6.8±0.6 mg cm-2 estimated by our photographic method.

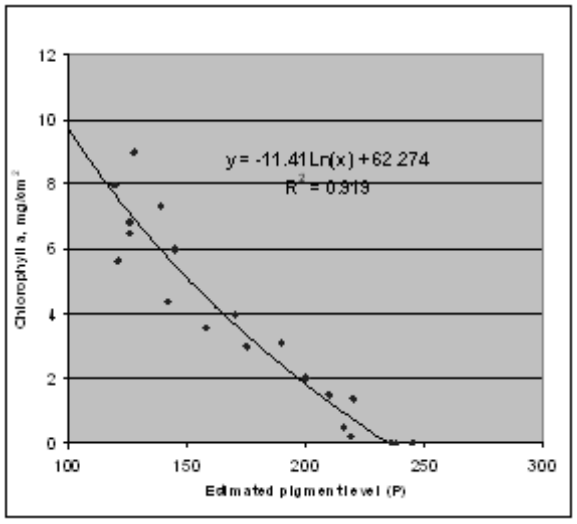

Figure 4: *The relation of estimated pigment level (P) to measured chlorophyll density. Data points are from different times during the bleaching and recovery processes*.

The usefulness of our method was further demonstrated by the results from monitoring the time course of the experimentally induced bleaching of *S. pistillata* fragments in the dark as described in the Methods section. A steady decline in chlorophyll density is seen until the 44th day, when the corals were completely bleached (Fig. 5).

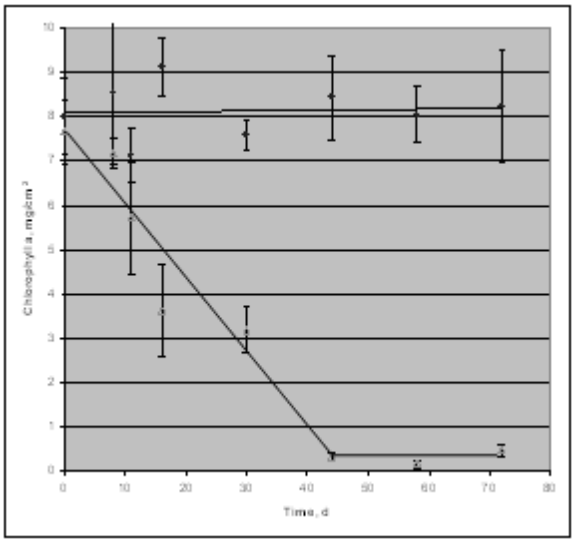

Figure 5: *Photographically estimated chlorophyll density of bleached fragments △ vs. control ● (n=5). The bleaching was complete by day 44 (as seen in the graph)*..

A calibration curve should be determined for each coral species, since the distribution of the zooxanthellae between polyp body and tentacles, the depth of algae within the calyx, and the surface rugosity, are all species-specific properties that affect

the relationship between the photographically estimated chlorophyll and its true areal concentration. Put in a different way, the color of a zooxanthellate coral, as it appears to the eye or camera, depends not only on the pigment concentration but also on its distribution over the coral surface. If the conditions under which the image is taken (distance, light, exposure, background, and camera) are changed, a new calibration curve should be generated. It is also important to take all such photographs with the tentacles in the same stage, either withdrawn or expanded, since tentacle status considerably affects the optical properties of corals (Levy et al. 2003).

The advantages of the method are obvious: once calibration is established, the tedious and error-prone tissue homogenization, pigment extraction, and area determination procedures are no longer required. Furthermore and most important, our method is totally nondestructive, rapid, inexpensive, readily computerizable and transmissible.

We believe that this bioassay can be further developed for use even on the reef scale, as long as photographic activity is done under similar conditions regarding distance and angle of the camera in relation to the reef, solar elevation, cloud cover, wave height, tidal state, etc.

By using this bioassay, one can gather information on reef status by relatively simple and inexpensive tools. We hope that this will encourage scientists and government officials to support the creation of an extensive worldwide network monitoring the health of reefs in real time, and including most remote and poorly explored reef areas.

4) SeaMester, P.O. Box 5477, Sarasota, FL, 34277

Abstract. Due to severe and ongoing population declines, *Acropora palmata* received US federally threatened status in 2006. NOAA has since released a protocol for demographic monitoring of this genus in order to assess population status, and to encourage monitoring partnerships throughout the Caribbean (Williams et al 2006). In 2006, NOAA partnered with the SeaMester program to include monitoring sites along their sailing routes, including the British Virgin Islands (BVI), Bequia (St. Vincent Grenadines), and Green Island (Antigua). Monitoring data collected by the SeaMester program in the BVI are presented here, along with NOAA monitoring data from Curacao (Netherlands Antilles). Six fixed *A. palmata* monitoring plots were established in BVI, and 9 were established in Curacao. Within these plots, 12-15 randomly selected colonies have been measured annually and examined for signs of disease, predation, and other notable conditions. Live area index (LAI), and white syndromes, snail predation, and damselfish territory prevalence were statistically compared between the two regions. The relatively user-friendly protocol coupled with basic field trainings with partners allowed for substantial spatial expansion of this monitoring program. This broader monitoring coverage is needed to guide prioritized Caribbean-wide management based on observed population condition and resilience.

Key words: *Acropora*, demographic monitoring, *Coralliophila*, *Stegastes*.

Introduction

The elkhorn coral, *Acropora palmata*, is a spectacular shallow-water branching coral species that offers structural framework, protective habitat, and tourist-appeal to coral reef ecosystems. Like many other coral reef species, disease and bleaching events, hurricanes, and stressors associated with coastal development have driven dramatic population declines over the past 40 years (Gladfelter 1982, Nagelkerken and Nagelkerken 2004, Boulon et al 2005).

In response, *A. palmata* and congener, staghorn coral (*A. cervicornis*), were listed as threatened under the US Endangered Species Act (ESA) in May 2006 (NMFS 2006). To satisfy the ESA mandate for regular status updates, the National Oceanographic and Atmospheric Administration (NOAA) released a protocol for *Acropora* spp. demographic monitoring (Williams et al. 2006). The protocol aims to directly document population status, and to apply findings to management activities. Also, the protocol was designed to promote collaborative monitoring partnerships throughout the Caribbean.

Material and Methods

In January 2006, education staff from the SeaMester program volunteered to participate in monitoring efforts along its Caribbean sailing route, which provided a unique opportunity to address the significant gap in *A. palmata* monitoring and research in the eastern Caribbean. After receiving field training and guidance from the protocol authors, staff and students from the SeaMester program initiated *A. palmata* monitoring off Virgin Gorda and West Dog Island (British Virgin Islands), Bequia (St. Vincent Grenadines), and Green Island (Antigua). These complement existing NOAA monitoring locations in the Florida Keys, Puerto Rico, Navassa Island, and Curacao (Netherlands Antilles) (See Fig. 1). Results presented here will focus on monitoring efforts in Curacao and the BVI.

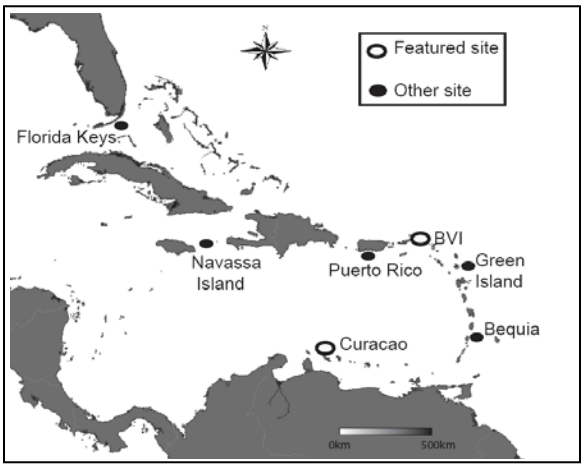

Figure 1: Current *A. palmata* demographic monitoring sites.

Detailed monitoring methods are available in Williams et al. (2006). In each monitoring region, we located 2-3 reef areas with moderately dense *A. palmata* colonies (avoiding thickets and isolated colonies). In these areas, we haphazardly established three 7m radius permanent monitoring plots, and within in each plot, 12-15 colonies were randomly selected for tagging and detailed monitoring. Each tagged colony has been annually measured, and examined for signs of disease, predation, bleaching, fragmentation, growth anomalies and other notable conditions.

Using size measurements, we calculated a live area index (LAI) for each tagged colony, where: LAI= $((\text{length} \times \text{width} \times \text{height})/3)^2 \times$ % live. This served as an index (not a direct estimate) of change in colony live tissue coverage. Importantly, LAI generally underestimates actual surface area, and this underestimate increases with colony complexity.

When additional resources were available, we also conducted annual total live tissue inventories (including recruitment) within each plot, genotype analysis, growth measurements, and exploratory regional mapping.

Datasets and photographs were received within one month of each monitoring event conducted by SeaMester staff and students. NOAA staff regularly addressed field questions, and datasets were quality-assured by verifying observations with colony photographs and through discussion with the observers.

We compared Curacao and BVI datasets for: a) white syndrome prevalence (including white-band disease (WBD), white pox (WPx), and rapid tissue loss (RTL)), b) average colony live area index (LAI), c) snail (*Coralliophila abbreviata*) predation prevalence (defined by regions of exposed, clean white skeleton along the colony live tissue edges), and d) three-spot (*Stegastes planifrons*) damselfish territory prevalence (defined by live tissue 'chimney' structures topped with algal tufts (Fig. 2).

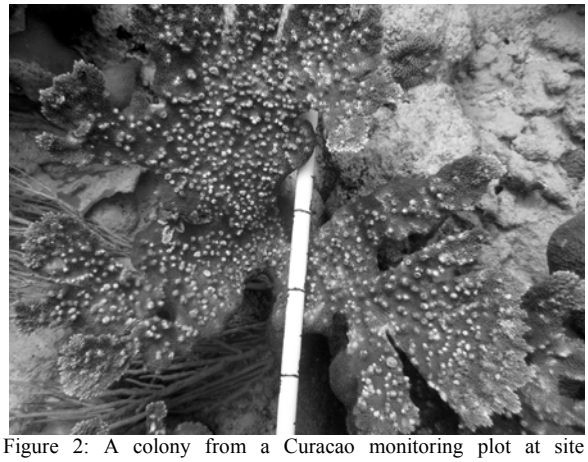

Figure 2: A colony from a Curacao monitoring plot at site 'SeaAqrm' impacted by an extensive three-spot damselfish (*S. planifrons*) territory. *S. planifrons* repeatedly bites areas of live coral tissue, which heal and overtime become chimney-like structures topped with fleshy macroalgae.

Datasets were first tested for normality and homogeneity of variance (Levene's test), and if needed, transformed ($\log_{10}$, square-root) to correct for failed assumptions. Usable datasets were statistically compared using a repeated measure (annual) hierarchical design ANOVA with survey plot nested within site and region.

Results

Live Area Index (LAI): Colony assemblages in the BVI and Curacao were very distinct, which was reflected in the live area index (LAI). A typical colony in the monitored areas of Curacao was relatively large, with many long branches, and low partial mortality (resulting in a high LAI). A typical colony in monitored areas of the BVI was small and mostly encrusting with sometimes a few short branches, and a moderate level of partial mortality (resulting in a low LAI). LAI varied significantly by region, and was twice as high for Curacao plots (Fig. 3). LAI increased slightly at all plots between 2006 and 2007.

Disease Prevalence: White syndrome (WPx, WBD, RTL) prevalence varied significantly by year and by region (Fig. 4). In 2007, white syndromes affected 23.9-56.9% of monitored colonies in Curacao, compared to 19.4-36.0% in 2006, and to 0-2.8% for the BVI in 2006. By 2008, white syndrome prevalence in Curacao fell to 14.6-29.3% of colonies affected, and healing lesions were frequently observed.

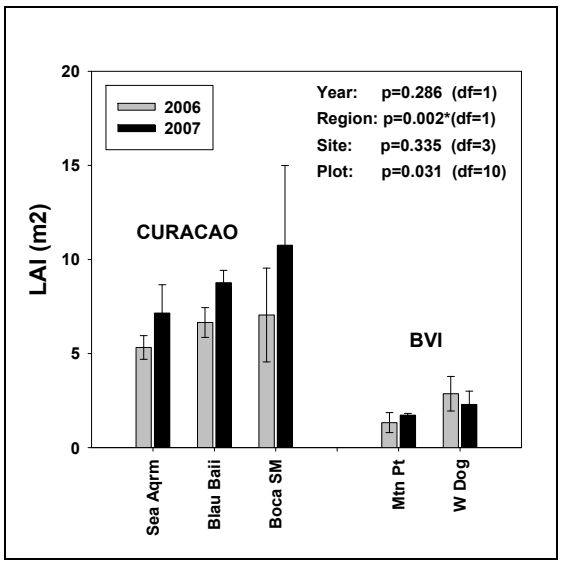

Figure 3: Mean colony live area index (LAI) (±1 SE) for *A. palmata* colonies in Curacao and the BVI in 2006 and 2007. *Indicates a statistically significant factor.

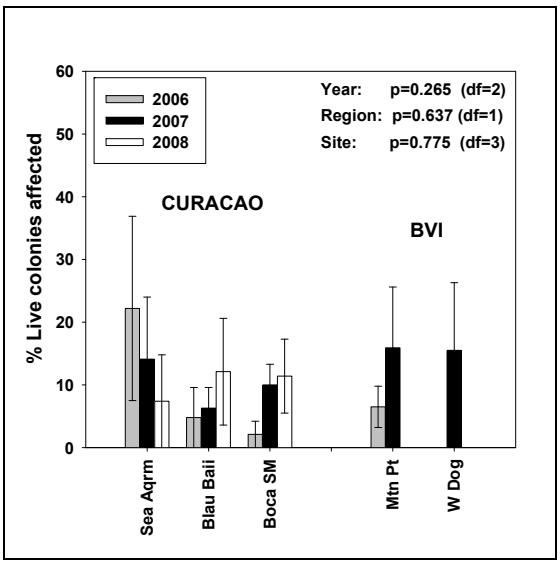

Figure 5: Mean prevalence (% live colonies affected) of snail (*C. abbreviata*) predation in Curacao in 2006-2008 and the BVI in 2006-2007 (±1 SE).

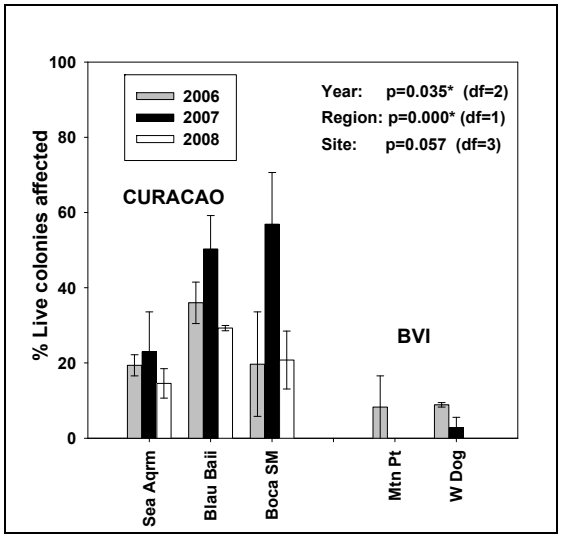

Figure 4: Mean prevalence of white syndromes (WBD, WPx, RTL) affecting *A. palmata* colonies in Curacao in 2006-2008 and the BVI in 2006-2007 (±1 SE). *Indicates a statistically significant factor.

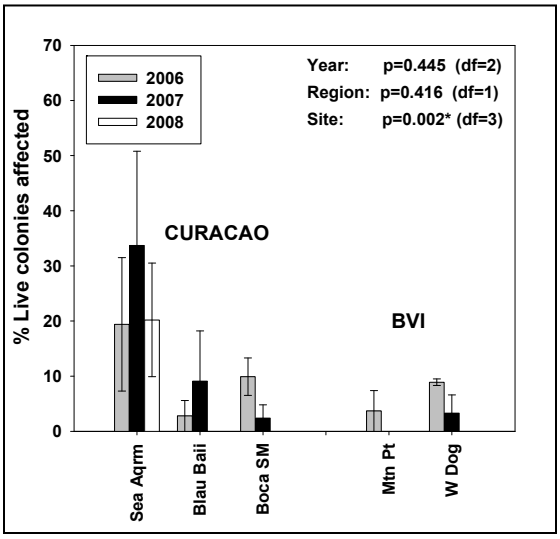

Figure 6: Mean percentage of *A. palmata* colonies impacted by three-spot damselfish (*S. planifrons*) territories in Curacao in 2006-2008 and the BVI in 2006-2007 (± 1 SE). *Indicates a statistically significant factor.

Snail Predation: The prevalence of live tissue grazing by the coral-eating snail, *C. abbreviata,* ranged from 2.1-22.2% of monitored colonies affected in Curacao, and 0-15.9% in the BVI. Predation prevalence was highly variable, and did not vary significantly by year, region or site (Fig. 5).

Damselfish Territories: Three-spot damselfish (*S. planifrons*) territories varied significantly by monitoring site (Fig. 6). Prevalence was generally low at all sites (ranging from 0-9.9% of monitored colonies affected, except Curacao site 'SeaAqrm,' which ranged from 19.4-33.7%) (Fig. 2, Fig. 6).

Discussion

Monitoring and Management: Regional differences in *A. palmata* populations, such as observed differences in 'reactions' to and recovery from threats, can have important implications for managers. Population variability based on the surrounding environment, habitat-driven morphology (Hubbard 1988), and genetics (Baums et al. 2005) allows certain populations to flourish under varying 'threat' circumstances. Regional monitoring programs such as this one can track population responses to threats, can assist managers in appropriate mitigation, and can

potentially help predict the likelihood of population survivorship, allowing managers to prioritize accordingly (Vardi et al. 2008).

Typical colony morphologies in Curacao and in the British Virgin Islands were very distinctive; an average colony in monitored areas of Curacao was relatively large and frondose, while a typical colony in BVI plots was small and mostly encrusting, sometimes with a few short branches. These morphology differences resulted in significant differences in LAI (Fig. 3), and can have important implications for asexual fecundity in this species (Fong and Lirman 1995, Williams et al. 2008). Thus, a typical colony in Curacao would be expected to yield greater asexual recruitment in a moderate storm or other fragmentation event, which suggests that the population is relatively better able to sustain itself reproductively. Importantly, LAI generally underestimates actual surface area (particularly for more complex colonies) (Williams et al. 2008), so the regional difference in actual live tissue was probably greater.

Monitored areas in Curacao recovered well following frequent White pox (WPx) observations. In 2007, white syndromes (usually WPx, but also sometimes WBD) affected 23.9-56.9% of monitored colonies in Curacao, compared to 19.4-36.0% in 2006, and to 0-2.8% for the BVI in 2006. By 2008, white syndrome prevalence in Curacao fell to 14.6-29.3% of colonies affected, evidence that colonies were able to overcome WPx, at least on the short-term. Partial mortality from WPx lesions in 2007 was often still visible on the affected colonies during 2008 surveys, but was usually characterized by an advancing line of live tissue working toward the center of the old lesion.

The long-term effects of three-spot damselfish territories are not well understood. In this study, territory prevalence was generally low at all monitored sites, ranging from 0-9.9% of colonies affected, except for Curacao site 'Sea Aqrm,' which hosted significantly more territories, ranging from 19.4-33.7% (Fig. 2, Fig. 6). Subsequent annual surveys will likely shed light on the long-term consequences of these territories on *A. palmata* colony condition.

Snail predation was low to moderate at the monitored sites (Fig. 5), ranging from 2.1-22.2% of monitored colonies affected in Curacao, and 0-15.9% of affected in the BVI. In areas with substantial *A. palmata* population declines, such as the Florida Keys, *C. abbreviata* grazing activities have been shown to be particularly detrimental, as snail density and predation increased on surviving colonies (Miller et al 2002). Observations of detrimental snail predation can potentially serve as justification for emergency removal by managers (Miller 2001). Snail predation will continue to be monitored at all sites.

Volunteer Involvement in a Monitoring Program: Threatened and endangered species receive a great deal of attention from the media, often creating public interest and volunteers willing to assist with fieldwork. This enthusiasm can potentially dramatically expand the spatial scale of regional monitoring studies. However, channeling this interest and participation into scientifically meaningful and consistent data can be challenging. For the *Acropora* spp. monitoring protocol (Williams et al. 2006), our successful partnership with the SeaMester program in the British Virgin Islands was facilitated by field trainings with experts during monitoring plot set-up and initial surveys. The SeaMester program was an ideal volunteer partner because of its on-board education staff with a background in marine biology, and because it allowed us to gather consistent data from remote areas that would otherwise be inaccessible.

Observations and data collected by SeaMester and other collaborators are always documented photographically, allowing NOAA staff to quality-assure data by reviewing a subset of observations (including all unusual observations). Any questions from the field crews were addressed as quickly as possible, and a consensus was obtained prior to final data entry.

The protocol (Williams et al. 2006) is designed with various levels of participation options, based on the time and expertise constraints of potential collaborators. Even if a potential partner is only able to collect very basic monitoring data, odd or alarming observations can serve as an 'early warning system' for further investigation by dedicated field teams.

Demographic *Acropora* spp. monitoring requires field training and advanced scuba diving abilities, particularly for *A. palmata* surveys (relative to surveys of *A. cervicornis*, which tends to inhabit deeper reef areas, and is slightly more compact and less structurally delicate). Monitoring sites are usually very shallow, and located along at the reef crest where wave energy and surge is maximized. Volunteers are required to have a certain degree of buoyancy expertise in order to conduct monitoring activities safely and without damaging corals.

Broad scale monitoring projects like this one offer a unique chance at understanding regional differences in *Acropora* spp. population response to a variety of challenges. As global climate change, disease outbreaks, and coastal development continue to affect the Caribbean region, our broader knowledge of *A. palmata* can potentially guide prioritized Caribbean-wide management based on observed regional population condition and resiliency.

Acknowledgements

Financial support for our monitoring work has come from the NOAA Coral Reef Conservation Program and the NMFS Southeast Regional Office. Efforts in Curacao initiated from and were supported by a grant from Royal Caribbean International (Adventure of the Seas) and the Education and Research Department of the Curacao Sea Aquarium. Many thanks for field support in Curacao from Andrea Anton, Lyza Johnston, Steve Piontek and the Education staff of the Curacao Sea Aquarium. Thanks to the SeaMester program coordinators who facilitated this monitoring effort, and to students that assisted with fieldwork.

Abstract. Widespread accumulation of mud on nearshore hardbottom was recorded during biological monitoring surveys for beach nourishment projects from Cape Canaveral to Miami along the Florida Atlantic coast and from Naples to St. Petersburg along the Florida Gulf of Mexico coast following the hurricanes of 2004. Permanent video transects were used for this study along with in-situ measurements of mud layer thickness. The surveys have indicated deposition of a relatively thin layer of fine sediments over extensive areas of hardbottom and thick accumulations at the base of sharp relief features. Storms suspend this fine material, resulting in turbid nearshore waters for long periods. The high adhesive capacity of the mud particles has enabled sediments to survive as a compact layer through the winter storms of 2004 through 2008. The effects have been lethal for many filter-feeding species while photosynthetic activity and recruitment opportunities are reduced for most benthic species. The 2007 monitoring data suggests significant mortality of octocoral recruits due to the smothering effects of mud, indicating that octocorals are not surviving beyond two to three years in this environment. It is hypothesized that the sediments were transported by hurricane-generated waves and currents from the deeper parts of the shelf.

Key Words: hurricanes, mud, recruitment, corals, octocorals

Introduction

Reefs and hardbottom communities with variable representation of scleractinian coral species and coral cover are widespread in the upper shelf of Florida. Between August 14 and September 26, 2004, four hurricanes (Charley, Frances, Ivan, and Jeanne) impacted the Florida shelf and coastline. Following these storms, widespread accumulation of mud on nearshore hardbottom and reefs was recorded from Cape Canaveral to Miami along the Atlantic coast and from Naples to St. Petersburg along the Gulf of Mexico (Gulf) coast. The nearshore distribution of mud is very wide with water depths ranging from 3 meters to at least 15 meters, and the offshore distribution ranges from approximately 50 to 60 meters to 1-2 kilometers from the shoreline. Very nearshore accumulation is characteristic of areas where vertical escarpments face the shoreline, such as Indian River County on the Atlantic side and Collier County on the Gulf side of Florida (Figure 1). Distant offshore accumulation was recorded in the Gulf of Mexico where the shelf is characterized by a very low gradient.

The mud has accumulated in a range of forms: relatively small pockets of a few decimeters in width in concave areas; attached to or perched on top of reefs and hardbottom ridges, subvertical to overhanging escarpments (ledges) and knolls; and a thin veneer of mud over sand, hardbottom and reefs. The thickness of accumulated mud varies from a few millimeters to over a meter. The content of the mud is variable with a visually higher carbonate component in south Florida in comparison to northern areas. For example, the mud in Indian River County is darker than the mud observed in Broward County.

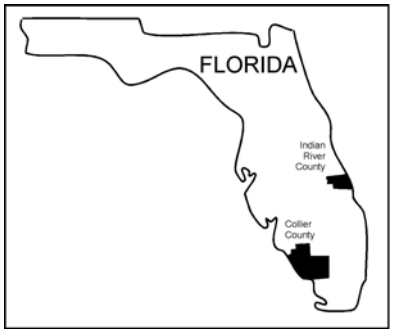

Figure 1. Location map of Florida counties mentioned in text.

The high adhesive capacity of the mud particles has enabled sediments to survive as a compact

layer through the winter storms of 2004 through 2008. Shallow nearshore locations are characterized by high wave energy. Storms suspend this fine material, resulting in turbid nearshore waters for long periods. Mud accumulations persist in these areas, both as a thin veneer over hardbottom and hardbottom communities and as thick accumulations (Fig. 2a). In some locations along the Indian River County shoreline, (central Florida Atlantic coast), accumulations of more than 20 cm in thickness were observed along the inshore edge of hardbottom at the base of scarps and ledges. The surveys have also indicated the deposition of a relatively thin layer of fine sediments over extensive areas of hardbottom. As a result, the visibility in nearshore waters has been dramatically reduced for several years. The summer of 2007 was the first opportunity of adequate water clarity for aerial photography to discern the shallow water hardbottom features in Indian River County.

Methods

Annual measurements of mud accumulation were performed from 2006 through 2008 on a nearshore artificial reef constructed as mitigation for impacts to nearshore hardbottom from a beach restoration project in Indian River County. Permanent transects were established for the evaluation of benthic community succession on the artificial reef. Monitoring methods involved permanent video transects and photo surveys with *in-situ* measurements of mud layer thickness to study the dynamics and effects of mud on benthic succession.

Two types of artificial reef were constructed as mitigation for impacts to nearshore hardbottom habitat: high-relief, high-complexity (HRHC) reef and low-relief, low-complexity (LRLC) reef. The high-relief, high-complexity artificial reef was designed to have a vertical relief of 0.9 to 1.8 m. Limestone boulders were partially stacked to achieve this vertical relief. The low-relief, low-complexity mitigation reef was designed to mimic a vertical relief of 0.3 to 0.6 m using a single layer of limestone boulders. The mitigation reef was constructed between May and September 2004; however, artificial reef placement could not be completed due to the passage of hurricanes Frances and Jeanne in September 2004. Therefore, a portion of the high-relief reef and the main portion of the low-relief reef were constructed in the summer of 2005. This phased construction enabled us to compare the influence of mud on benthic ecological succession.

Results

Accumulations of mud up to 30 cm in thickness were measured along the inshore edge and within spaces between boulders of the pre-hurricane artificial reef during the Year 1 baseline survey in August 2006. A thin cover of mud was also observed on the subhorizontal surfaces of the boulders. During the July 2007 survey, the mud persisted and was redistributed in a slightly thinner layer throughout the artificial reef, migrating into areas which had not been previously affected by mud. During the 2006 baseline survey, mud was not recorded on the post-hurricane high-relief reef; however, in July 2007, mud accumulations were recorded on this portion of the artificial reef. In July 2008, mud pockets increased to 15 cm in thickness along the portions of the post-hurricane reef constructed in 2005. Overall, mud accumulation is deeper along the western edge of the mitigation reef as compared to the eastern (i.e. seaward) edge.

The persistence of the mud layer on the pre-hurricane high-relief reef has led to the extensive development of cyanobacterial mats (Fig. 2b). The development of cyanobacterial mats is a very typical feature of mud accumulation throughout the study area. Mud-related cyanobacterial growth has had a dramatic smothering effect on octocoral recruits (*Leptogorgia* spp.) on the artificial reef. The total number of octocorals along the permanent transects decreased from 56 in 2006 to 16 in 2007. The surviving colonies suffered from partial coverage of cyanobacterial mats, and tissue loss and mortality were observed under epiphytic overgrowth (Fig 2c). A similar effect was observed in southeast Florida; however, a small number of *L. virgulata* colonies survived for several years despite partial burial by mud.

In 2006 and 2007, the dominant functional group on the post-hurricane artificial reef was fleshy macroalgae. Overall percent cover of macroalgae at the post-hurricane high-relief reef in July 2007 was 77.6% compared to an overall average of 5.3% at the pre-hurricane high-relief reef (Fig 3). The macroalgal community on the pre-hurricane reef was initially dominated by calcareous algae due to its ability to survive under a veneer of sediments. A turf algae/cyanobacteria matrix replaced calcareous algae as the dominant functional groups on the pre-hurricane artificial reef in July 2007.

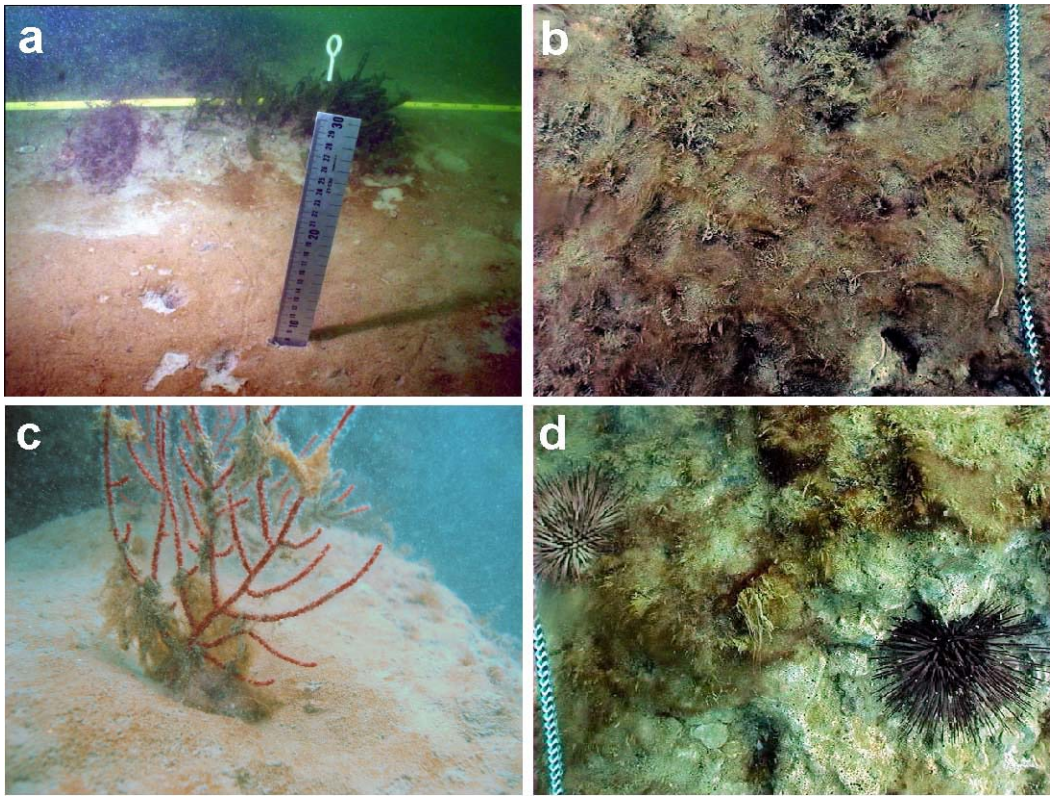

Figure 2. a) Mud layer of 8-10 cm covers extensive areas of hardbottom at depth of 5 m, offshore of Sarasota County, FL; b) Cyanobacterial mat over a thin layer of mud covering both substrate and algae on the pre-hurricane artificial reef, Indian River County, FL; c) Accumulation of mud flakes on octocoral, *Leptogorgia hebes,* stimulate growth of cyanobacteria and algae which smother octocoral tissue; d) Sea urchins scrape mud and cyanobacteria, exposing clean limestone surface for recruitment opportunities.

The 2007 survey revealed a three-fold increase in the sea urchin population on the artificial reef in comparison to 2006 (118 versus 37). The number of urchins (*Arbacia punctulata* and *Echinometra lucunter*) along the six permanent transects increased to 296 in 2008.

The increase in the urchin population is positively correlated with the increase in coral recruitment between 2006 and 2008. Ten small coral colonies (<2 cm in diameter) were recorded during the 2007 survey compared to two colonies in 2006. Twenty-one *Oculina* sp. colonies were counted along the six video transects during the 2008 survey. *In situ* counts along one of the 20-meter monitoring transects on the pre-hurricane reef documented 32 *Oculina* sp. recruits <2 cm in diameter during the July 2008 survey.

Discussion

The 2006 and 2007 annual surveys have demonstrated that mud deposition has had a greater effect on benthic succession and community composition than the difference in vertical relief in the Indian River County artificial reef. The continual resuspension and deposition of mud on the benthic community on the reef constructed in 2004 (pre-hurricane) has resulted in recurrent disturbance events which limit macroalgal colonization and growth.

Scleractinian corals are a minor component of the nearshore hardbottom community in Indian River County and are generally represented by only three species, *Siderastrea siderea*, *Oculina varicosa* and *Phyllangia americana*. Recruitment and survival of small colonies has been inhibited by mud deposition on both the natural nearshore hardbottom and artificial reef in Indian River County. However, the proliferation of sea urchins on the artificial reef between 2006and 2008 has increased recruitment opportunities. Sea urchins remove the mud and cyanobacterial mats while grazing, exposing clean limestone surface available for coral recruitment (Fig. 2d). The high density of *Oculina* recruits in the 2008 survey was observed in areas of bare substrate scraped clean of mud by urchin activity. In comparison, no coral recruits were observed along this transect during the 2007 survey.

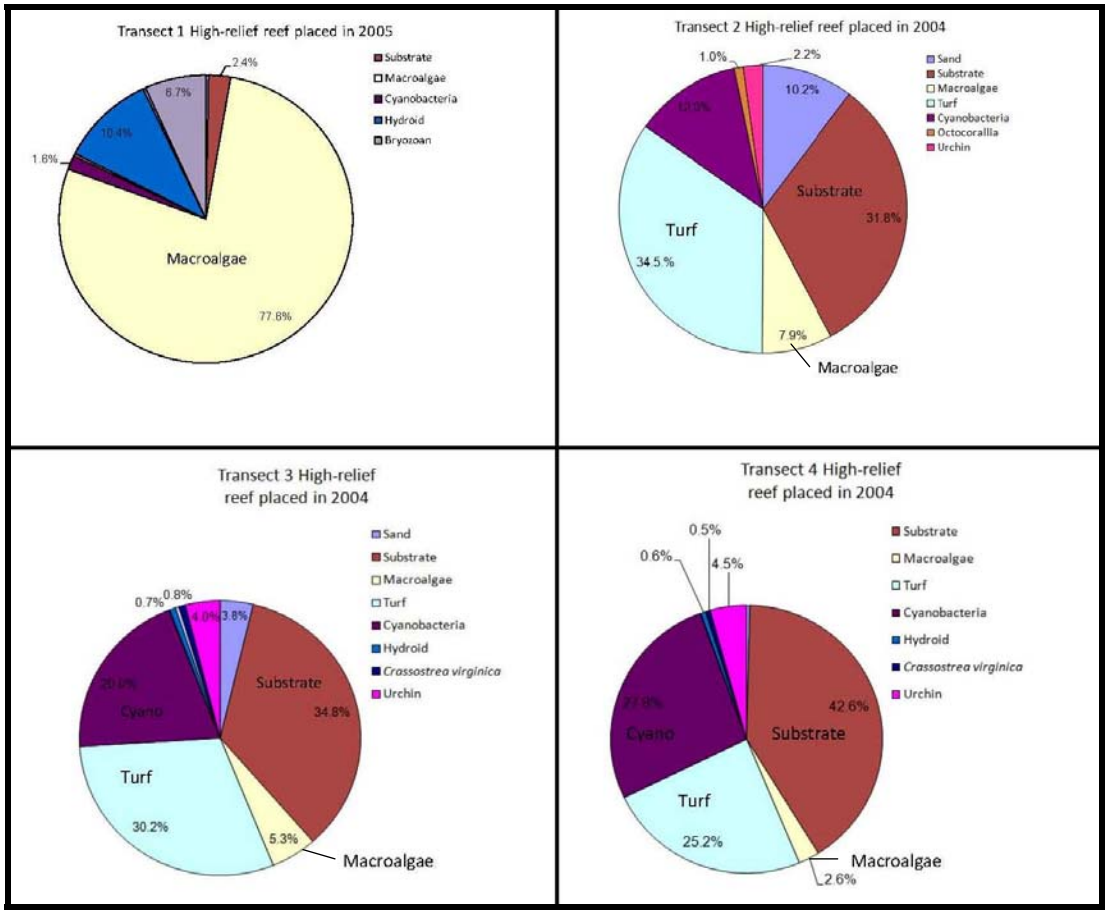

Figure 3. Percent cover of the major functional groups on the Indian River County artificial reef. Note dominance of macroalgae on the post-hurricane reef versus substrate and cyanobacteria on the pre-hurricane reef. Survey date is July 2007.

Scleractinian corals are a considerably larger component of hardbottom communities in southwest Florida; however, scleractinian coral diversity is low. The most common species are *Siderastrea siderea*, *Solenastrea bournoni* and *S. hyades*, *Cladocora arbuscula* and *Phyllangia americana*. The impact of mud on corals varies considerably for the same species with colony size, shape, location in nannorelief features and depth of mud layer.

Siderastrea siderea and *Solenastrea* spp. are notorious for their tolerance to turbid water and sedimentation. However, this mud event has resulted in an overwhelming accumulation of fine material which has remained within hardbottom areas for several years. Larger, vertically-developed colonies exhibit higher survivorship than encrusting and flat colonies, which can undergo fission and partial mortality. Corals are actively removing mud from their surface, and mud particles are continually resuspended by wave and current action. Continuous active sediment removal slows growth rates since energy is diverted to mucus production and particle removal rather than feeding and photosynthesis/ symbiosis, potentially resulting in coral death (Riegl and Branch, 1995).

Cladocora arbuscula forms small colonies less than 10 cm in diameter. *C. arbuscula* colonies are typically less than 5 cm high in Collier County. Several colonies of *C. arbuscula* were observed buried and dead while some were partially buried and dead. The cryptic species, *Phyllangia americana*, settles and grows mostly on subvertical and overhanging features, avoiding sedimentation impacts associated with horizontal surfaces. During our three years of post-hurricane surveys in Collier County, the only coral species observed recruiting within the areas of nearshore mud accumulation was *P. americana*.

The effects of mud deposition have been lethal for many other filter-feeders while photosynthetic activity and recruitment opportunities have been reduced for most benthic species. Small sponges (for example, *Cinachyra alloclada,*), zoanthids, Actiniaria, tunicates, etc. were observed dead under mud cover throughout the study area on both the Gulf and Atlantic sides of Florida. For example, 30 tunicates were recorded on the pre-hurricane high-relief artificial reef in Indian River County in 2006, while in 2007, only 5 tunicates were recorded along

the same permanent transects. Under normal conditions, exponential growth of cover by tunicates during the first few years of succession is a characteristic feature of artificial reefs in South Florida.

Conclusions

It is hypothesized that the mud was transported by hurricane-generated waves and currents from the deeper parts of the shelf, where this material normally accumulates. We cannot suggest any other source for such an enormous amount of mud to be transported during such short-term events such as hurricanes. Large accumulations of mud were observed in southeast Florida in 1960 after Hurricane Donna at depths of 25 to 45 meters. These accumulations were later removed by currents and waves (E. Shinn, personal communication). Shinn et al. also described the deposition of mud layers over ooid sands in the very shallow realm of banks south of Joulters Keys and Cat Key in the Great Bahama Bank after Hurricane Andrew in August 1992 (Shinn et al., 1993).

Our observations of mud in Collier County and Palm Beach County are similar to the descriptions of interlacing mud with coarse post-hurricane sand described by Shinn et al. (1993). It is possible that the impacts of mud on reefs and hardbottom communities are more widespread than suggested by our observations and surveys. It is not possible to evaluate the extent and consequences of this impact on benthic communities and individual groups of organisms without considerable additional study. However, it is clear that the effects are long-lasting.

We have observed that mud masses are able to move along or around features; however, we are uncertain if the sediments are moving as liquid, gel-like body or are resuspended and accumulate in adjacent areas in the leeward side of relief features. The latter appears to be more plausible; however, the sediment dynamics have not been studied. The redistribution and accumulation of mud in the areas of the Indian River County artificial reef constructed after the hurricanes of 2004, which were previously unaffected by mud deposition, are clear evidence that the mud masses are mobile in the nearshore environment.

Population status of *Acropora* corals in the Florida Keys

S.L. Miller[1], M. Chiappone[1], L.M. Rutten[1], D.W. Swanson[2]

1) University of North Carolina-Wilmington, CMS, 515 Caribbean Drive, Key Largo, FL 30337, USA

Abstract. Population declines of staghorn coral (*Acropora cervicornis*) and elkhorn coral (*A. palmata*) are often-cited examples of Caribbean reef change since the 1970s, due, in part, to disease and localized effects from storms and predation. Both corals were listed as threatened on the U.S. Endangered Species List based upon range-wide decline and poor recovery. A spatially intensive survey undertaken in the Florida Keys of *Acropora* corals quantified habitat distribution, colony abundance, size, and condition at 235 sites spanning over 200 km in 2007. A two-stage stratified sampling design using belt transects incorporated cross-shelf habitats and no-fishing management zones from < 1 m to 15 m depth. *A. cervicornis* was widely distributed among sites and habitats and was particularly abundant on patch reefs, with up to 1.22 colonies/m^2 and surface area coverage of 2%. *A. palmata* was abundant on shallow spur and groove reefs, with up to 1.25 colonies/m^2 and surface area coverage of 25%. Although the prevalence of disease is relatively low, both species continue to suffer predation, as well as physical impacts from lost fishing gear. Predicting the future of these corals in Florida requires information about both their present-day ecology and geologic history in Florida.

Key words: *Acropora*, benthic, coral, marine protected area, population, stratified sampling.

Introduction

The declines in abundance of two of the principal Caribbean reef-building corals, staghorn coral (*Acropora cervicornis*) and elkhorn coral (*A. palmata*), are often-cited examples of the changes in western Atlantic reefs that have occurred during the past several decades (Bruckner 2002; Gardner et al. 2003). The causes of these declines, which began in the late 1970s, include large-scale factors such as coral bleaching and disease, especially white band disease (Gladfelter 1982), as well as smaller-scale effects from storms and predation by corallivorous snails and damselfishes (Miller et al. 2002). Both coral species were under consideration for addition to the U.S. Endangered Species List since the early 1990s and were determined to be "threatened" based upon range-wide population declines and poor recovery (*Acropora* Biological Review Team 2005).

Although there is increased awareness of the fragility of Atlantic *Acropora* corals to further potential population decline, there is surprisingly little information on density structure, size, and population abundance for wider Caribbean reef areas. Notable exceptions to this pattern include recent population assessments of *A. palmata* in the U.S. Virgin Islands, southern Caribbean, and in the Florida Keys at one reef (Miller et al. 2002; Mayor et al. 2006; Zubillaga et al. 2008). While some recovery is apparent in localized areas, populations of both species remain depressed well-below historical levels, including the Florida Keys (Dustan and Halas 1987; Porter and Meier 1992), and threats continue that will potentially inhibit population recovery (*Acropora* Biological Review Team 2005).

To ascertain the current population status of both *Acropora* species, we conducted an intensive assessment of the spatial distribution, colony abundance, size, and condition of both species throughout the Florida Keys, including a large area of the Florida Keys National Marine Sanctuary (FKNMS) and Biscayne National Park (BNP) during 2007. The surveys were an outgrowth of previous efforts conducted by the authors dating back to 1999 to quantify the abundance and condition of coral reef benthos throughout the FKNMS. Data obtained from these earlier efforts, together with existing habitat mapping information for the FKNMS, were used to guide the sampling of *Acropora* corals along ~200 km of the Florida Reef Tract. The goals of the survey were to determine patterns in habitat distribution, coral colony density, colony size, condition, and total population abundance estimates (Miller et al. 2007).

Material and Methods

During June-August 2007, surveys at 235 sites were completed along ~200 km of the reef tract from northern Biscayne National Park to SW of Key West (Fig. 1). Previous surveys dating back to 1999 aided in optimizing a sampling plan for obtaining abundance and size distribution estimates for the two *Acropora* corals. A two-stage stratified random sampling design incorporated nine unique habitat

types (Table 1), as well as areas inside and outside of FKNMS no-take zones. The statistical design features are detailed in Smith et al. (in press).

To control for spatial variation in population abundance metrics, we divided the Florida Keys survey domain into strata based upon: 1) habitat class; 2) geographic region; and 3) management zones of the Florida Keys National Marine Sanctuary (FKNMS) and Biscayne National Park (BNP). Cross-shelf habitats were designated using regional benthic habitat maps (FDEP 1998). The habitat classification scheme accounted for features that correlate with benthic fauna distributions, including cross-shelf position, topographic complexity, and the proportion of sand interspersed among hard-bottom structures. A geographic regional stratification variable was used to account for oceanographic and geological features in the Florida Keys that influence the distribution, community dynamics, and biotic composition of reefs (Marszalek et al. 1977; Shinn et al. 1989). FKNMS no-take zones were incorporated as a third stratification variable that delineated areas open and closed to consumptive activities.

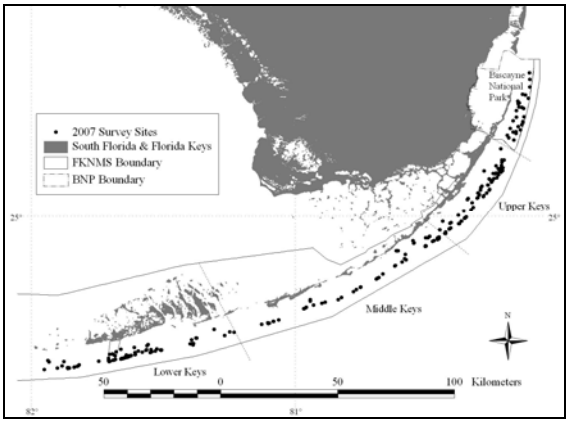

Figure 1: *Acropora* coral sampling locations in the Florida Keys.

A geographic information system (GIS) containing digital layers for benthic habitat (FDEP 1998), bathymetry, and no-take marine reserve boundaries was used to facilitate delineation of the sampling survey domain, strata, and sample units. Map resolution was such that the survey domain was divided into a grid with individual cells of size 200 m by 200 m (40,000 m^2) that defined unique habitat classes (Table 1). A two-stage sampling scheme following Cochran (1977) was employed to control for spatial variation in population metrics at scales smaller than the grid cell minimum mapping unit. Grid cells containing targeted reef and hard-bottom habitats were designated as primary sample units. A second-stage sample unit was defined as a belt transect of fixed area (15-m x 1-m in dimension) within a primary sample unit. The size of an individual primary sampling unit allowed divers to swim to the location of any given second-stage sampling unit from a moored or anchored vessel.

Table 1: Characteristics of study sites in the Florida Keys sampling domain. Available sites reflect the number of 200 m x 200 m cells containing particular habitat types based upon FDEP (1998)

Habitat	Depth (m)	Sites (% effort)	Sites available
Mid-channel patch reef (MPR)	0.9-2.7	36 (15.3)	3,532
Offshore patch reef (OPR)	2.1-14.6	42 (17.9)	1,170
Hard-bottom matrix	2.7-5.8	4 (1.7)	79
Shallow hard-bottom (LHBS)	2.7-7.0	25 (10.6)	972
Inner line spur and groove (IRT)	1.5-6.1	8 (3.4)	87
High-relief spur and groove (HSG)	0.6-9.4	51 (21.7)	238
Deeper hard-bottom (LHBD)	6.7-13.7	15 (6.4)	1,962
Patchy hard-bottom (PHBD)	4.6-11.3	21 (8.9)	956
Low-relief spur and groove (LSG)	7.6-16.2	33 (14.0)	2,825
Sampling Design Total	0.6-14.6	235 (100)	11,821

The underwater surveys consisted first of locating randomly selected, pre-determined coordinates with a differential global positioning system. The original sampling list included 180 sampling locations, with an additional 145 alternate sites. If the original waypoint was not the intended habitat, we sampled the closest alternate site. Once on-site, a two-person benthic diver team oriented four transect tapes 15 in length, marked in 1-m increments, along the bottom, and surveyed an area 0.5-m out from each transect side. Transects were placed in a haphazard fashion, but in a way that adequately represented the habitat at the randomly selected site coordinates. Once transects were deployed, divers determined the depth range along the transect using a digital depth gauge, as well as the maximum vertical relief using a 50-cm scale bar. Any *Acropora* corals that were observed within the 15-m x 1-m belt transects were counted, measured, and assessed for colony condition. For this study, a colony was defined as a patch of continuous live tissue (ramet). In cases where a skeletal unit, possibly representing a single genet, was divided into one or more patches of tissue with clearly defined boundaries, each patch was considered a separate ramet. Measured dimensions of ramets were used to estimate colony surface area using applicable surface area formulas. The condition measurements included an assessment of bleaching, disease, predation, and overgrowth by algae, sponges, and other biota.

Statistical estimation procedures for population abundance metrics (proportional transect frequency, density, total abundance) for a two-stage stratified random sampling design were adapted from Cochran (1977), and computations were carried out using SAS statistical software. Domain-wide mean and variance estimates of density were obtained from weighted averages of strata means and variances. A stratum weighting factor was the proportion of the stratum area relative to the overall survey domain (see Table 1). Similar procedures were used to estimate proportions such as frequency of transect occurrence. Stratum abundance (absolute number of colonies) was estimated by multiplying stratum density by stratum area. The same principle was used to estimate the variance of stratum abundance. Domain-wide abundance and associated variance were obtained by summing the respective strata estimates over the entire survey domain. Design estimation of means, proportions, totals, and their associated variances does not depend on the probability distribution of the underlying observations (Cochran 1977). As such, statistical testing for differences is done by constructing confidence intervals directly from standard errors of either a stratum-specific or domain-wide metric. Statistical comparisons of means were conducted by calculating confidence intervals (CI) based upon the equation CI = mean ± t[α, df] * SE (standard error), with SE estimated by the two-stage stratified sampling design (Cochran 1977). Confidence intervals were adjusted for multiple comparisons using the Bonferroni procedure. While this adjustment made for relatively conservative statistical testing, it reduced the probability of spurious significant pair-wise comparisons. The experiment-wise error rate was held at α = 0.05 and the comparison-wise error rate was adjusted based on the number of multiple comparisons (comparison-wise error rate = α /c, where c = k (k-1)/2). Colony abundance estimates structured by habitat and by colony surface area size were computed using the two-stage design (Cochran 1977).

Results

Staghorn coral (*Acropora cervicornis*) was observed in the general survey area at 55 of the 235 sites (23%) and was recorded within belt transect boundaries at 45 sites (19%). The habitat distribution of *A. cervicornis* was broader than *A. palmata*, with colonies found in all but one of the nine habitats (Fig. 2). *A. cervicornis* was frequently encountered on mid-channel and offshore patch reefs, as well as inner line reef tract sites, and by comparison was infrequently encountered on the deeper fore reef. Statistical comparisons of proportional transect frequency yielded a significance difference (P < 0.002, Bonferroni-adjusted α) between offshore patch reefs and low-relief spur and groove. A total of 508 *A. cervicornis* ramets were counted and mean (± 1 SE) colony density (no. ramets per m^2) ranged from 0.094 ± 0.030 on offshore patch reefs to ≤ 0.01 in four of the lower-relief fore reef habitats (Fig. 2). The greatest mean (± 1 SE) site level densities (0.683-1.217) occurred on mid-channel and offshore patch reefs. Despite this variation, no significant differences (P > 0.002, Bonferroni-adjusted α) in mean colony density among habitats were detected. Abundance estimates indicate that there are perhaps ~13.8 ± 12.0 million *A. cervicornis* colonies in the sampling domain, with nearly 90% on mid-channel and offshore patch reefs (Table 2).

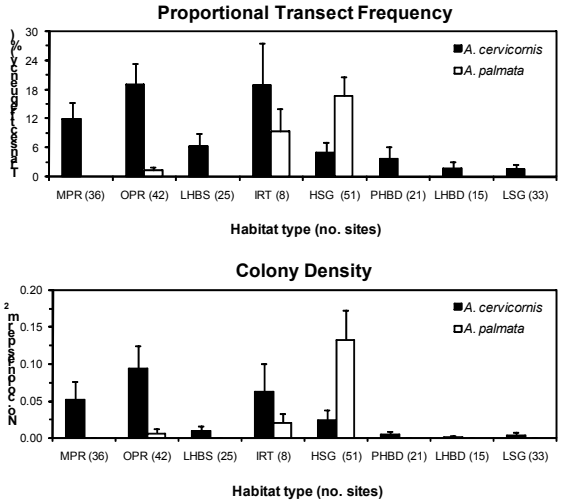

Figure 2: Mean proportional transect frequency (% of transects present) and colony density (no. colonies per m^2) for *Acropora cervicornis* and *A. palmata* in the Florida Keys. Error bars are +1 SE and numbers in parentheses on the x-axis are the number of sites sampled in each habitat. See Table 1 for habitat abbreviations.

Most *Acropora cervicornis* colonies were relatively small (< 0.5 m in max. diameter), although there were some mid-channel and offshore patch reefs with larger thickets. The percentage of live tissue surface area per m^2 of substratum was greatest on several mid-channel and offshore patch reefs, with upwards of 2% cover at individual sites. Mean ± 1 SE percent cover by habitat type was < 0.2% for all habitats, with offshore patch reefs (0.16 ± 0.06%), inner line reef tract (0.11 ± 0.06%), and mid-channel patch reefs (0.10 ± 0.05%) yielding the greatest habitat-level cover, albeit at very low values. Population abundance estimates structured by ramet surface area indicate that ~67% of the *A. cervicornis* colonies in the Florida Keys are less than 150 cm^2 in surface area (Fig. 3). Of the colonies assessed for condition, there were no obvious signs of white band disease, white plague, tissue necrosis, or *Coralliophila* predation.

Nine colonies (2.2%) had obvious signs of damselfish predation. Entanglement with lobster trap rope was common, especially on patch reefs, and of the 78 patch reefs sampled, more than 90% of sites, including Sanctuary no-take zones, contained remnant lobster trap debris. There were several instances where *A. cervicornis* colonies were entangled and obvious tissue damage and colony breakage resulted.

Table 2: Population abundance estimates (95% CI) for *Acropora cervicornis* and *A. palmata* in the Florida Keys sampling domain partitioned by habitat type. See Table 1 for habitat abbreviations

Habitat	*A. cervicornis*	*A. palmata*
MPR	7,391,961 (6,586,650)	0 (0)
OPR	4,656,900 (2,955,347)	295,989 (545,865)
LHBS	388,849 (406,738)	0 (0)
IRT	217,527 (270,435)	72,509 (80,934)
HSG	224,028 (269,877)	1,266,381 (744,035)
PHBD	237,554 (344,767)	0 (0)
LHBD	106,458 (213,021)	0 (0)
LSG	550,372 (958,157)	0 (0)
Total	13,773,647 (12,004,991)	1,634,879 (1,370,835)

Elkhorn coral (*Acropora palmata*) was observed in the general survey area at 24 of the 235 sites (10.2%) and was recorded within belt transect boundaries at 19 sites (8.1%). The habitat distribution of *A. palmata* was much narrower than its congener, with colonies found along belt transects in three of the nine habitats (Fig. 2). *A. palmata* was most frequent on high-relief spur and groove reefs and statistical comparisons of proportional transect frequency illustrated a significance difference between this habitat and five of the other habitats surveyed ($P < 0.002$, Bonferroni-adjusted α). A total of 403 *A. palmata* ramets were counted and mean (± 1 SE) colony density (no. ramets per m^2) ranged from 0.133 ± 0.039 on high-relief spur and groove to zero in five habitats (Fig. 2). The greatest mean (± 1 SE) site-level densities (0.833-1.250) all occurred in high relief spur and groove; this habitat type yielded a significantly greater mean colony density than five of the other seven habitats ($P < 0.002$, Bonferroni-adjusted α). Abundance estimates indicate that there are perhaps ~1.6 ± 1.4 million *A. palmata* colonies in the sampling domain, with nearly over 80% occurring on high-relief spur and groove reefs (Table 2).

Acropora palmata colony sizes showed a significantly greater range compared to its congener, and we were encouraged to find several sites with relatively large (> 0.5 cm diameter) colonies. High-relief spur and groove reefs yielded the largest colonies and percent cover values. Although mean percent cover on the 51 high-relief spur groove reefs sampled was 1.6 ± 0.6%, site-level cover was greater than 8% at several reefs and ranged up to 25%. These sites yielded the largest colony sizes, with several sites yielding mean surface areas of > 1,000 cm^2 per colony. Population abundance estimates structured by ramet surface area indicate that although ~50% of the *A. palmata* colonies in the Florida Keys are less than 250 cm^2 in surface area, many larger colonies still remain (Fig. 3). Of the *A. palmata* assessed for condition, ~5% were affected by predation by *Coralliophila* snails and damselfishes. We were discouraged to find lobster trap rope entangled in thickets of live colonies, including some within Sanctuary no-take zones, but were encouraged by the absence of visible diseases such as white band and white pox.

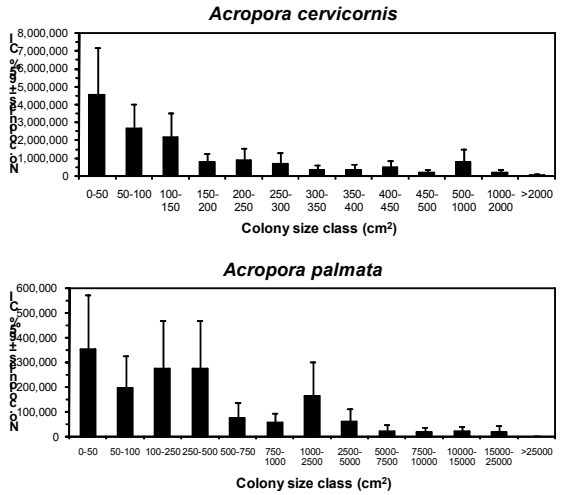

Figure 3: Population abundance estimates by ramet surface area for Florida Keys *Acropora cervicornis* and *A. palmata*. Error bars are 95% confidence intervals. Note the abundance scale change between the two species.

Discussion

This effort is one of the few studies to conduct population estimates of any coral species among a diversity of habitats representing a range in cross-shelf position and depth. For western Atlantic *Acropora* corals in particular, we are aware of only a handful of studies that attempted to derive total colony abundance estimates structured by habitat type and/or colony size (e.g. Miller et al. 2002; Mayor et al. 2006; Zubillaga et al. 2008). Population census results from a large area of the south Florida shelf indicate that both *Acropora* species are aggregated in particular habitat types, especially on the outer platform margin, in habitats noted for historically significant thickets of colonies. However, site-level densities were well below 1 colony/m^2 for both species at most sites sampled, and it is clear that the abundances of these corals are currently far below historical reports in the study area (Dustan and Halas 1987; Porter and Meier 1992). These results are similar to other studies in the region (Bruckner 2002; *Acropora* Biological Review Team 2005).

Acropora colony size distributions were skewed towards mostly smaller (< 100 cm^2) colonies, although larger thickets, especially *A. palmata*, were still present at some locations, especially in high-relief spur and groove habitats. Disease prevalence and evidence of predation from damselfishes and gastropods were low (« 1% of all colonies). We were encouraged to find relatively extensive thickets of *A. palmata* at several bank reefs scattered throughout the Florida Keys, and most of these reefs are currently zoned as no-take marine reserves. However, physical damage from derelict fishing gear, especially trap debris, poses what we believe to be a significant and ongoing impact to extant colonies, even within Sanctuary no-fishing zones.

Population abundance estimates for the Florida Keys illustrate considerable spatial variability, but nonetheless indicate that there are perhaps millions of extant colonies of each species in the study area, not including thickets of *A. cervicornis* to the north of the reef tract offshore of Ft. Lauderdale. At the same time, genetic diversity may be relatively low for both corals and is clearly a research need. Coupled with life history factors, lower genetic diversity may render both corals susceptible to ongoing impacts from storms, disease, and predation, suggesting that current conditions are perhaps not conducive to the recovery of both corals to 1960s or 1970s "baseline" levels (Williams et al. 2008).

What is apparent from these data is that the distribution and abundance patterns of the two species are clearly different, perhaps necessitating different management approaches. Although 34 different spur and groove reefs, including inner line reef tract, were sampled, our results indicate that significant *A. palmata* stands remain at only a handful of sites. While most of these sites are within existing FKNMS no-take zones, predation by snails and damselfishes, as well as physical impacts from lost fishing gear, is prevalent. The distribution pattern of *A. cervicornis* reflects the importance of patch reefs to the possible recovery of this species, which contrasts with historically abundant stands on the deeper fore reef. While there are over 5,000 patch reef sites on the south Florida shelf, *A. cervicornis* is very patchily distributed, and the factors responsible for this pattern are not well known. Promising management options for the recovery of *Acropora* corals have not been well defined, yet there are obvious actions that can be taken at the local level to enhance survival of existing populations that include removing fishing debris and minimizing the potential for further impacts to reefs.

Abstract. A four-year study collected the first comprehensive time-series data from a small Red Sea fringing reef located at the extreme northernmost latitude of tropical coral reefs. Corals here are exposed to 2-6° C daily water temperature changes with seasonal variations exceeding 14-16° C, and salinities between 43 and 45 ppt. Annual reef surveys included random photo quadrats, fixed video transects, and environmental measurements. In just four years, this pristine reef ecosystem was subjected to nearby shipping-port construction, rapid coastal urbanization, a bleaching event, and an oil spill. Results indicate that of the approximately 35 coral taxa known to survive here, just six compose 94% of those on this reef. Between 2004 and 2007, statistically significant changes were found in reef health indicators including a 50% increase in dead coral, 58% increase in sea urchins, and decreases in biodiversity and fish abundance. Despite all this, corals here appear to be well adapted to extreme environmental conditions. This ongoing research establishes a reference point for coral reef studies in this region and will be key to future local conservation efforts.

Key words: Red Sea, fringing reef, Gulf of Suez, marginal reefs, oil spill, bleaching, salinity extremes.

Introduction

The impact and rate of change of manmade influences on pristine fringing coral reefs, as well as the organisms that inhabit them, are not well documented. Fringing reefs grow close to shore in relatively shallow water and few fringing reefs remain in good health due to their accessibility and proximity to pollution sources. Although Red Sea reefs are cited among the most diverse in the world (Loya 1972), Red Sea corals are not well studied (Rinkevich 2005). Oceanographic and biologic data and long-term coral reef studies in the Gulf of Suez are nearly non-existent.

The reef investigated (dubbed "Zaki's Reef" after the first author's grandfather) is located in the Red Sea's Gulf of Suez near the most northern latitude for subtropical coral reefs. The very shallow (50 - 80 m deep) Gulf of Suez lies adjacent to an extremely arid desert where rainfall is minimal, evaporation rates are high, and freshwater inputs are non-existent. The persistent trade winds and extreme temperatures result in high salinity (43-45‰) and large daily and seasonal temperature fluctuations. High temperatures and salinity reduce oxygen solubility, which can stress many species of reef-dwelling organisms. The organisms that thrive here must be able to tolerate these environmental extremes. A recent study (Moustafa 2000) estimated that 335 species of corals are found in the Red Sea, yet only 35 species have been identified in the Gulf of Suez.

There are no known long-term studies investigating fringing reefs in the study area prior to the research reported here. Therefore, the main goal for this study was to establish a knowledge base for fringing coral reefs in the Gulf of Suez and provide basic information for future reef management, as reef-related activities generate a significant portion of Egypt's tourism revenue.

The effects of natural and manmade influences on a pristine, isolated fringing coral reef located at an extreme northern latitude were documented annually for four summers. Pollution from shipping and oil spillage pose a significant threat as does rapidly expanding coastal urbanization and other anthropogenic influences new to the region. Specific objectives were to: 1) assess reef condition and identify dominant coral taxa; 2) identify local natural and manmade stressors, 3) assess the reef's resilience to recent natural and manmade influences; 4) document changes in indicators of reef health including incidence of disease; 5) conduct annual fish surveys; 6) evaluate reef sediment components; 7) assess water quality, and 8) share results since data on this region are nearly nonexistent.

Material and Methods

Zaki's Reef is a small fringing reef (approx. 0.8 km x 0.1 km) located in Gulf of Suez (29° 32' N and 32° 24' E). The reef averages only one to two meters in depth at mean low tide, and can be accessed by a short swim

from the beach (Fig. 1). Methodologies used to sample this reef followed universally accepted protocols (Hill and Wilkinson 2004). Underwater videography was repeated annually (Page et al. 2001) to document changes along five 10m transects located across the reef (Fig. 2). Fish surveys were conducted by visually logging and digitally recording taxa and their abundance during five-minute observation periods at three of the 10m transects.

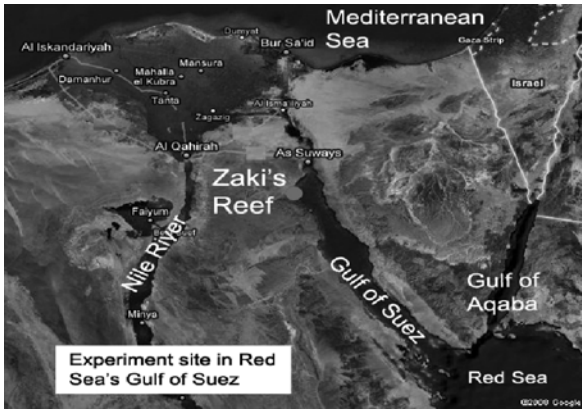

Figure 1: Location of Zaki's Reef in the Red Seas Gulf of Suez, approximate 80 km south of the highly trafficked Suez Canal.

A reef-wide random quadrat (0.5 m^2) photo survey captured bottom substrate from across the reef to establish spatial variation, percent coral cover, diversity, and dominance. Quadrat survey swim direction and distance were randomly determined from the roll of two dice. Each year, statistics for percent bottom coverage by coral taxa were derived from the analysis of approximately 120 randomly collected quadrat photos.

Accessory measurements included salinity and pH measured across the reef annually. Underwater sensors provided temperature readings every 15 minutes at locations across the reef. Air temperature was also obtained during 2006 and 2007. Local tides, wind, weather, dolphin sightings, ship traffic, and oil offloading were regularly logged during fieldwork. Water samples were collected from across the reef and were shipped to Florida International University for water-quality analysis.

Hand grabs of surface-sediment samples were collected from the beach to just offshore of the reef to determine grain-size distributions. Sediment grain-size analysis was performed by manually sieving dried sediment hand grabs into size classes and calculating class weight percentages. The biogenic composition of approximately 100 sand-size grains from each sample was identified under a microscope. The number of coral grains, foraminiferal shells, coralline red algal fragments, gastropods, calcareous algae, echinoid spines, worm tubes, and other skeletal fragments was tabulated and SEDCON Index (SI) was calculated as a measure of reef health (Daniels 2005) where: P_c = number of coral grains, P_f = larger, symbiont-bearing foraminifera, P_{ah} = coralline red algae, gastropods, calcareous algae, echinoid spines, worm tubes, and other skeletal fragments and P_u - unidentifiable grains.

$$SI = (10*P_c) + (8*P_f) + (2*P_{ah}) + (0.1*P_u)$$

Data Analysis: Each year, the sharpest digital images were extracted from all transect and quadrat survey data to identify coral taxa and calculate percent benthic cover. We used a Red Sea comprehensive guidebook (Myers and Lieske 2004) to identify fish and coral taxa. Coral Point Count (CPCe) software (Kohler, 2006) was employed to evaluate coral coverage along each 10m transect by analyzing 25 consecutive frames representing an approximately 0.5 m x 2m wide area of coverage. Percent coral cover was calculated by identifying the bottom type at 60 randomly generated points projected onto each frame. Statistical analysis showed that data from 60 points was statistically identical to identifying the total coverage area from each photo. For each quadrat photo, the total surface area (cm^2) covered by each coral taxon was determined using CPCe software. Coverage analysis included identifying and counting fish, long- and short-spined sea urchins, and sessile organisms.

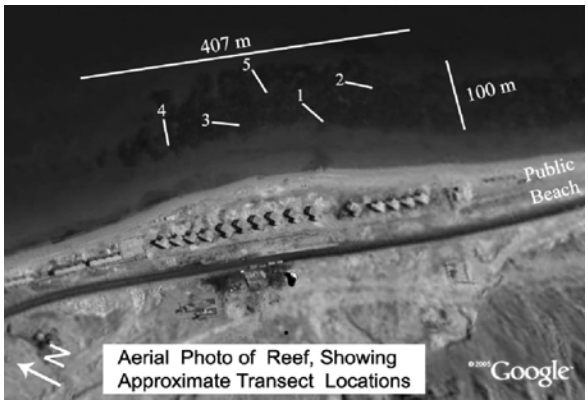

Figure 2: Satellite photo depicting Zaki's reef and the locations of five 10m transects monitored annually since 2004. Newly constructed villas can be seen on the reef's beach.

Results

Coral Taxa and Coverage: Each year percent bottom cover by coral and other parameters were compared to 2004 baseline survey data (Fig. 3). On average, of the 35 coral taxa identified in the Gulf of Suez, only six groups make up 94% of the coral cover on Zaki's Reef, with approximately 80% being hard and 20% soft corals. Dominant hard corals include *Acropora humilis, A. microclados,* and *A. hemprichii*

(staghorn), *Litophyton arboretum* (neptheids), *Stylophora pistillata* (finger), as well as *Porites columna* and P. *plantulata* (anemone) corals. On average, 25% of the coral (mainly *Acropora*) were dead in 2004. This value increased to 33% dead by 2007. Spatial patterns of coral cover and fish surveys indicate that offshore regions of the reef, where water is deepest, are typically healthiest and most diverse.

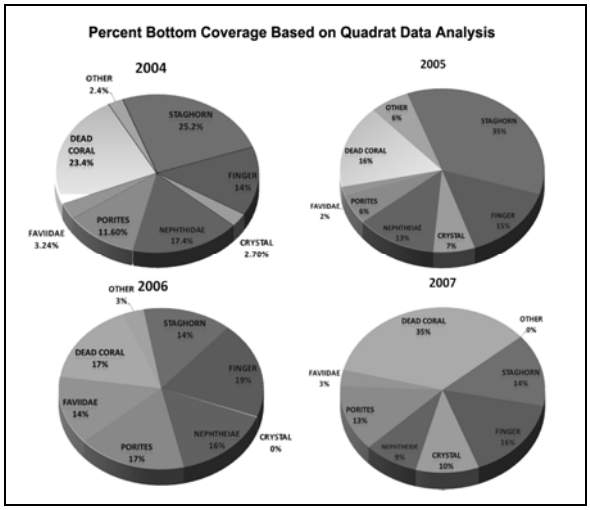

Figure 3: Percent change in coral cover over four years based on the random 0.5 m^2 quadrat survey 2004-2007. Note the increase in dead corals by 2007.

Averaged over four-years, random quadrat survey results indicate that *Acropora* spp. dominate (22.2% ±5.08 SE), followed by *Stylophora pistillata* (16.1% ±1.14 SE, *Litophyton arboreum* (13.5% ±1.92 SE), and *Porites* spp. (11.9% ±2.31SE). Mean dead coral coverage over the four-year study was 22.8% (±4.3SE). The remaining major groups, Faviidae (*Echinopora fructiculosa* and *Platygyra daedalea*, and *Galaxea fascicularis* (crystal coral), were roughly equally common, averaging 5.5% (±2.78SE) and 4.9% (±2.13SE), respectively.

Based on quadrat survey results, *Acropora* spp. were dominant (25%) in 2004 and increased to over 35% coverage in 2005. However, there was a huge decline for both *Acropora* (to 14%) and *Galaxea* (from 7% down to < 0.3%), between 2005 and 2006, yet there was no observed net change in percent dead coral that year (Fig. 3).

Video Transects. At all five transects, *Platygyra*, *Echinopora*, *Porites*, *Stylophora*, *Litophyton*, and *Acropora* corals were the dominant groups (Table 1). When 2007 coral coverage was compared to previous years, a net loss in coral was observed at Transects 2 and 4, while overall net increase was observed at the remaining three transects. The Kruskal-Wallis statistical test for population equality (Conover 1999) validated the null hypothesis that there was no significant difference in coral coverage at all transects over four years ($\alpha = 0.05$). Therefore, despite noted differences in species coverage between years (Table 1), differences remain statistically insignificant ($\alpha = 0.05$), indicating that as some species declined, others increased. Change in coral cover along Transect 3 over four years (Table 1) illustrate a shifting of corals as seen by a dramatic decline in *Platygyra* between 2004 and 2007. This was balanced by increase in *Porites*, *Stylophora*, and *Acropora*, while the overall amount of bottom substrate (dead coral and rubble) changed very little.

Table 1. Changes in percent coral cover at each 10 m- transect since 2004.

Percent (%) Change in Coral Coverage by Species at Each Transect

Ten meter transects surveys take across the reef each year indicate that Transects 1, 3, and 5 show an overall net gain in coral since the initial baseline survey in 2004 or -05, while Transects 2 and 4 reflect an overall decrease in coral and a greater increase in coral disease.					

Coral Diversity: The Shannon Weaver biodiversity index (Shannon, 1948) is an indicator of number of taxa and their evenness. Comparison over time from each transect and among transects indicated that biodiversity varied significantly between years in every instance ($\alpha = 0.05$) (Fig. 4).

Trends in this index varied depending on transect location and water depth, with the most marked increase in the index occurring at Transect 1 that lies furthest offshore. The greatest decreases in the biodiversity index occurred in 2006, one year after the oil-spill and the worldwide bleaching event.

Sediments: Sediment samples from across the reef indicate that grain-size distributions remained fairly consistent over time. In general, the finest sands are found in the reef trough and grade to coarsest offshore on the outer reef edge. Biogenic analysis of the sand fraction of each sample showed a change in the biogenic composition. Beginning with the 2005 data, the SI sediment index showed a statistically significant increase in coral fragments and fewer foraminiferal fragments.

Sea Urchins: Each year, long- and short-spine urchins were counted in quadrat photos with short-spine urchins being noticeably more abundant than long-spined taxa. While sea urchin population counts

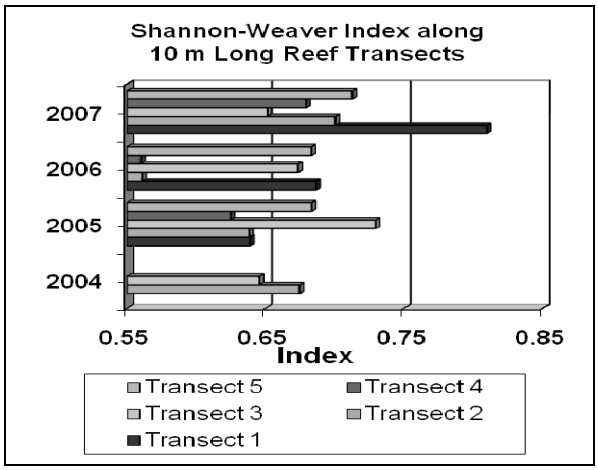

Figure 4: Calculated biodiversity index (Shannon Weaver) based on taxa present along five transects that range between 0.3 m and 3.0 m in depth.

were similar in 2004 and 2005, a notable, 42% increase in short-spine urchin was observed between 2005 and 2006, and a statistically significant increase of 58% between 2006 and 2007. No significant change was detected in the long-spined urchin population over the four years.

2005 Oil Spill: Immediate effects to the area in the days following the spill included increased turbidity, a clumping of oil in sediment and on rock faces, as well as a gummy residue on urchin spines. More than three years later, the effects of the 2005 oil spill were still widespread. Thick oil remained caked on rocks and the upper beach face, and was a few centimeters below the surface sediment on the reef and lower beach.

Temperature: Minimum and maximum daily air-temperature were 21ºC and 39ºC, respectively; an 18ºC difference. Daily underwater temperature range fluctuated between 0.3ºC and 4.5ºC. Seasonal water temperatures on the reef fluctuated widely between a low of 14ºC in February to a maximum of 34ºC in September. Shallower regions of the reef are markedly warmer and displayed greater daily variability than those in deeper water that experience stronger currents that allow for greater mixing.

Fish Bites, Coral Disease and Algae: Since 2004, annual digital photos documented a marked increase in fish bites, coral diseases, algae cover, and sedimentation on the reef. After 2006, an increase in parrotfish bites were observed on *Porites* corals, either territorial in nature, or possibly from remnant hydrocarbons in coral tissue attracting feeding (T. Goreau, pers. comm. 2008). Coral diseases were documented using photography beginning in 2006 and include *Porites* Ulcerative White Spot Disease and Pink and White Line Disease.

Water Quality: Average pH was 8.13 and average salinity was 44 ppt. Other analyses included total phosphorus (TP), soluble reactive phosphorus (SRP), total organic carbon (TOC), and dissolved inorganic nitrogen (DIN).

Discussion

At the outset of this research (2004), the reef was extraordinarily healthy and could be characterized as pristine. In 2005 a major oil spill occurred just three kilometers offshore of the reef during our field sampling. Although environmentally disastrous, it provided an opportunity to document reef conditions before and after an oil spill. This 2005 spill coincided with a widespread bleaching event (Lesser, 2007). Since 2005, new anthropogenic influences to this developing region of the Red Sea coastline included construction of a major shipping port, Port Soukna, less than 5 km north of the reef; a boom in seaside vacation homes within a few km of the reef; and the construction of villas on the reef's beach. In 2006, local fishermen staked claim on the beach at the southern portion of the reef for use as their port.

Table 2 summarizes known man-made and natural influences thought to be affecting this reef. The response of the reef community to recent stresses is mixed. In 2007, some positive signs of reef health were evident as three of the five monitored transects indicated an overall net increase in coral cover since 2004. On the other hand, since 2004, statistically significant differences were found in the amount of dead coral, urchin abundance, and biogenic components in the sediments. An increase in coral disease, fish bites, water turbidity, and sedimentation on corals, indicates a decrease in reef health.

Table 2. A subjective ranking of local influences affecting the reef.

Despite evidence that the reef continues to thrive, overall reef health deteriorated. Quadrat surveys showed a 50% increase in dead coral across the reef between 2006 and 2007. After the reef was stressed by the 2005 oil-spill and bleaching, corals appeared to be more susceptible to observed diseases and fish bites, similar to observations of Goreau and Wolf (2004). As petroleum hydrocarbons remain present in reef sediment, prolonged injury to this community

could continue for years and may explain much of the apparent decrease in overall reef health. The significant increase in short-spined urchins in 2007 is likely attributed to an increase in algae coverage.

We compared SRP and DIN in reef water samples to values reported in the literature (Lapointe et al. 1997). At nearly all locations, SRP levels were close to literature-reported values, while all DIN measurement, whose likely source is wastewater, exceeded literature's values by more than a factor of ten. The increased algal cover may be a response to these nutrients. Coral and mucus sampling for coliform bacteria were also positive.

Survival of this reef despite extreme environmental conditions clearly demonstrates its resilience over time. At the start of the study, results indicated that the reef was healthy and near pristine. Water visibility was high and sea urchin population counts were moderate. The sediment biogenic index initially suggested a healthy reef, and little coral disease was noted. Data from 2004/2005, prior to the oil spill, serves as a reference point, not only for this study, but also for any future coral reef studies in this region.

As man encroaches, human impact is no longer in question. Fishermen have relocated closer to the reef, beach houses that were under construction are being occupied, and with the new port, local shipping and oil offloading traffic has increased. Enormous tanker ships transiting less than 2 km away in very shallow water are displacing great amounts of sediment that appear to be contributing to reef sedimentation. The Gulf of Suez coastline to the north and south of Zaki's Reef is developing at an alarming rate without concern for the impact on the local environment.

Based on the existence of reefs in this region for the historic past, we can infer that select corals and their inhabitants can successfully thrive under extreme conditions. Corals and inhabitants here have adapted and appear more resilient to the large daily, seasonal, and interannual temperature variations and extreme salinities. Our results suggest that so far corals here are adapted to environmental variation and able to survive newly introduced stressors. Eventually, we anticipate that this reef will reach a point where it will no longer be able to recover from insults, and the community will succumb to the cumulative environmental impacts.

Abstract. Estimating reef fish species richness from underwater visual census (UVC) data has the potential to be negatively biased by non-detections of species present at a given site when the probability of detecting a species is less than one. To mitigate the effects of such sampling biases on subsequent ecological conclusions, we develop an occupancy model framework that estimates the probabilities of both detection and presence at locations in coastal Kenya using covariate logit-linear models. Based on a capture-mark-recapture (CMR) data structure for repeat observations over a closed sampling period, we find that reef-fish species characteristics are informative about differences in observed detection probabilities. Specifically, we show that schooling behaviour leads to higher probabilities of detection; that larger fishes are, on average, less detectable; and that detectability varies greatly by functional group. We also show how these characteristics of detection were poorly correlated with probabilities of occupancy and find that site-based covariates such as protection status may provide better models for presence. Finally we discuss the use of occupancy models in reef-fish surveys and suggest their use may be an important tool for reef ecologists in the future.

Key Words: mark-recapture; diversity; species richness; underwater visual census

Introduction

The diversity of coral reef fishes is unique in the marine environment and is among the characteristics that will most rapidly reflect fundamental changes in the ecological function of reef ecosystems. Although many alternate indices of diversity have been devised and used successfully in ecology (Buckland et al. 2005), species richness remains a prominent metric to describe the state of a given community (Kere and Schmid 2006). While species richness is frequently used to underpin the development of ecological theory, observing the true species richness of a given community is frequently difficult in practice (Dorazio et al. 2006) and, as a consequence of sampling error, the process signals contained in a given set of data may be weak or biased to an unknown degree (Allen and Starr 1982).

The potential for bias is particularly apparent in reef fish surveys where, for instance, small cryptic or large mobile species may not be readily observed due to low probabilities of detection in underwater visual census (UVC) data (Kulbicki 1998). Many reef ecologists recognize this issue and as a result the smallest and largest species on a given reef are frequently omitted from target species lists (McClanahan 1994). For the species that are present on target lists, detection probabilities are likely to be less than one (MacNeil et al. 2008b,a) and therefore fish species will have some probability of not being detected in a given survey, even over replicate transects at the same location. If detection probabilities are low, there may be many species present at a given location that remain undetected, negatively biasing the species richness observed to a substantial degree. Even though this issue is recognized conceptually, detectability is most often ignored during analysis and an implicit assumption is made that the probability of detection equals one.

Although most conventional sampling programmes do not address detectability directly in their design, model frameworks exist to address the issue of incomplete detectability during analysis. These models of species richness are based on capture-mark-recapture (CMR) models of tagged animals, whereby the probability of observing any given species on a particular transect is quantified relative to the detection histories of species observed during the survey, using a set of relevant covariates (Boulinier et al. 1998). Such an approach has been used successfully to estimate species richness in surveys of both birds (Kere and

Schmid 2006) and reef fish (MacNeil et al. 2008 a,b).

Although detection probabilities are important estimands in the quantification of species richness in UVC data, on their own they carry the implicit assumption that every species in the analysis was present at the sampling site during the census. For many species, this may not be the case, and the zeroes that arise in a set of UVC data can be due either to low probabilities of detection or because a given species was not present at a given sampling location. This second source of zeros has been called the occupancy state which, as it is either one (species present) or zero (species absent), can be quantified using presence-absence models combined with models for heterogeneous detection (MacKenzie et al. 2006). By combining models for detectability and occupancy, an analytical framework can be implemented to estimate species richness at a given survey location and, in the process, help to improve the ecological signal present in UVC data.

In this paper we use a well-known set of UVC data to demonstrate the conceptual utility of occupancy models to reef fish data. The statistical model presented describes separate components for handling the detectability and occupancy states of individual reef fish species, where covariate information from the species observed are used to estimate the proportion of a fixed species list that were not observed. The models are presented using a Bayesian inference framework.

Methods

To illustrate the applicability of an occupancy framework to reef fish UVC observations we selected data collected from coastal Kenya in the Western Indian Ocean (McClanahan et al. 2007). The collection of these data have been described elsewhere (McClanahan 1994) but briefly, the sampling scheme consisted of between 4 to 9 replicate UVC belt transects (5 m x100 m) conducted at four locations, two of which were protected from fishing (Mombasa; Malindi) and two of which were unprotected (Diani, Kanamai). Observations were made between 1992 and 2005, although sites were not surveyed in every year. The data were collected using discrete group sampling (DGS) where, depending on their physical and behavioural characteristics, fish from related groups or families were sampled on separate passes of a repeat transect in a given area. For these data, fish from eight families (Acanthuridae, Scaridae, Pomacentridae, Chaetodontidae, Pomacanthidae, Balistidae, Diodontidae, and Labridae) were counted to the species level using a fixed list of 161 potential species. Because the probability of losing or gaining new fish species among transects at a given site is near zero, the data permitted the mild assumption that the community was closed to species immigration and emigration over the sampling interval.

Occupancy models were built up from a conditional occupancy framework (MacKenzie et al. 2006) where, following conventional notation, y_i is the observed number of species detections accross k transects at a given site, ψ_i represents the probability of species i occupancy at a specific site, and θ_i represents the probability of detection for species j given that it is present at a particular site. The approach relates the occupancy state of species i to detectability using a two-part conditional model. First, if a species has not been observed ($y_i = 0$) then its occupancy state is unknown and can be described by

the sum of two conditional probabilities, the species being either not present ($\psi_i = 0$) or present ($\psi_i = 1$) but unobserved ($\theta_i < 1$):

$$p(y_i = 0) = \psi_i(1-\theta_i)^k + (1-\psi_i). \qquad (1)$$

Conversely, if the species is observed at least once over k transects ($y_i > 0$) then the record of events can be described as the bernoulli-distributed probability of occupancy times the binomial distribution of detections:

$$p(y_i > 0) = \psi_i \binom{k}{y_i} \theta_i^{y_i} (1-\theta_i)^{k-y_i}, \qquad (2)$$

for $y_i = 1, 2, ..., k$. Using these models as a basic structure for the detection of individual fish species, the framework can be extended to accommodate covariates of interest for ψ and θ using linear models and a logit link. For occupancy this is given by:

$$\frac{\psi_i}{(1-\psi_i)} = \beta_0 + \beta_1 x_1 + ... + \beta_j x_j, \qquad (3)$$

where the β's are covariate parameters for presence and similarly for detectabitliy:

$$\frac{\theta_i}{(1-\theta_i)} = \gamma_0 + \gamma_1 x_1 + ... + \gamma_j x_j, \qquad (4)$$

where the γ's are covariate parameters for detection. All of the γ's and β's are assumed to be $N(0,\sigma_j)$ distributed. Further details on this model and its implementation can be found in MacKenzie et al. (2006). Previous work on reef fish detectability has shown that schooling behaviour (schooling/non-schooling; SC); reef fish functional

group (FG; a grouping factor); and maximum total length (TL_{max}; a continuous variable) can affect probability of detection (MacNeil et al. 2008b,a). For simplicity, we used these three covariates in (4), the detection portion of our approach, to model the Kenyan reef-fish data and did not pursue covariate selection. In addition, we chose to include the same covariates in (3), as occupancy covariate selection has not been demonstrated previously and because our objective was simply to outline a form for the occupancy approach.

The resulting joint detection-occupancy model was implemented by Markov-chain Monte-Carlo (MCMC) simulation in the pymc (Fonnesbeck et al. 2008) toolkit for the Python programming language (Python Software Foundation 2006). Models were run for 15,000 iterations after a 15,000 iteration burn-in period and model convergence was assessed through visual inspection of parameter chains, where chains showing adequate mixing and stability were considered to have reached convergence.

Results

A range of between 34 and 84 species were observed across all transects, with consistently higher richness in the closed areas of Mombasa and Malindi. Observed occupancy proportions (Ω) were 23% or less in the open areas and were 34% or greater between the closed areas (Table 1). There was considerable year-to-year variation in richness values among sites, particularly for Mombasa which went from a high of 84 observed species in 1991 to a low of 55 observed species the following year.

Occupancy model convergence and mixing were good for all estimated parameters and all chains appeared to have reached convergence after the burn-in period. Posterior richness estimates ranged from 41% (66 spp.) to 74% (118 spp.) of the total species list, with estimates from 19% (31 spp.) to 41% higher than the observed proportions. There was slightly larger average estimated increases in richness in the closed (24%) versus the open (22%) areas. No sites showed evidence for all species being present, and the highest 95% credible interval bound lying at 83%.

Detection parameter estimates were highly variable among sites, with marked differences both between and among closed and open areas. Scrapevator detectability for example was relatively higher than site-averaged detectability in the closed areas, while being in the open areas. For other groups however (e.g. detritivores) detectability estimates were not consistent between management areas. The most detectable fishes tended to be grazers in the closed areas, and detritivores and invertivores in the open areas. Despite such evidence for differences among many functional groups, in many instances estimates spanned zero, suggesting additional covariates may be required to provide a satisfactory model of detectability at these sites.

Overall, the distribution of median estimated detection probabilities were more variable within open, as opposed to closed, areas. Kanamai in particular had a wider range of median detection probabilities across years relative to the other sites, with a somewhat diffuse distribution between zero and one that was apparent also in the Diani estimates. Conversely, the closed areas had more normally-distributed detection estimates, with median detectability values near 0.6 across years.

Unlike many of the detectability parameter estimates, fish characteristic parameter estimates were all poorly correlated with occupancy status, as almost all parameter estimates spanned zero. Exceptions to this included consistently lower planktivore occupancy in the open sites, and lower invertivore occupancy probabilities in Diani across all years. Although the covariate models were generally uninformative, the distribution of median estimated occupancy and detectability were consistently lower in the open versus closed areas. With the exception of Diani in 2006, the distribution of median estimated occupancy within sites was relatively consistent among years.

Median posterior estimates of detection and occupancy revealed distinct patterns in relation to median fish abundance per transect (Fig. 1). While sites with higher median abundance had clearly higher median probabilities of detection (Fig. 1a), median occupancy appeared (again with the exception of Diani in 2006) to be correlated with protection status rather than median transect abundance (Fig. 1b). To our knowledge, this has not been demonstrated previously.

Although detectability differences observed between open and closed areas are known to be highly correlated with abundance at a given sampling site (MacKenzie et al. 2006), probability of occupancy should be less so as a portion of this bias has already been expressed through the detection portion of the model. This appeared to be the case in our results, where only detection probabilities were shown to be highly correlated with median abundance at a given site.

Occupancy estimates on the other hand showed no such trend, instead reflecting unmodeled processes inherent in protection status that appear to have affected true species richness. Such processes may include effects of fishing on habitat quality that can reduce the occupancy probability of, for instance, coral-dependent species (McClanahan 1994). Indeed the lowest occupancy estimates consistently observed were for planktivorous species that, because they utilize the structural

complexity of the corals for shelter, are tightly linked to habitat conditions (MacNeil 2008) and likely to be directly affected by losses of reef habitat (Graham et al. 2008). The fine-scale resolution of species characteristics and their effects on detection and occupancy remain to be seen however, and we hope that the results presented here will generate new hypotheses in this area.

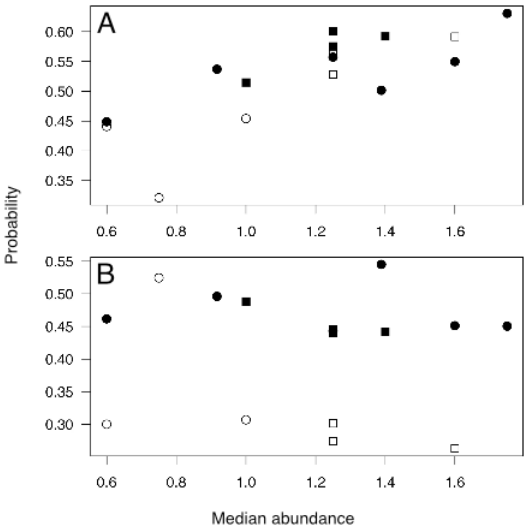

Figure 1: Median posterior detection (A) and occupancy (B) probabilities per median abundance of fishes observed per transect at Diani (open circle), Kanamai (open square), Malindi (filled square), and Mombasa (filled circle).

Given these results, we believe that occupancy estimates more directly reflect true trends in species richness through time than raw counts, as bias driven by the local abundance of fishes has, in part, been handled through modeling of detectability. Although these characteristics are evident in these data, it will require additional validation through both simulation and field studies to determine the efectiveness of occupancy models for informing management.

Discussion

We have outlined a general framework for estimating reef-fish species richness from conventional UVC data in which the issue of incomplete detection (a form of sampling error) is addressed directly using a conditional statistical model. The strength of the analysis is in the explicit parameterization of occupancy, where probabilities of presence can readily be linked to any potential covariates of interest on a given reef. While the occupancy models we developed from fish physical characteristics showed little correlation with occupancy probabilities, there is exceptional potential for occupancy models to link probabilities of presence with more likely covariates such as habitat characteristics (MacNeil 2008).

The covariates we chose, developed to deal with reef-fish detectability (MacNeil et al. 2008b,a) performed poorly in estimating occupancy, suggesting that fish physical characteristics are much more likely to affect detection probabilities than occupancy. If occupancy models are to be used routinely in reef-fish UVC surveys, covaraites must be identified that correlate appropriately with occupancy status. The presences or absences of particular reef fish species have been repeatedly linked to the site-scale habitats in which they are observed (Caley et al. 2001; Gratwicke and Speight 2005) and this suggests that reef-fish occupancy will most likely reflect trends in site-level characteristics. Although such an analysis has yet to be put into practice, our results show tentatively that protection status is a potentially informative covaraite, supporting the role of MPA's in promoting diversity.

That observed species richness is greatly affected by sampling bias due to the characteristics of the fishes observed has been widely recognized in reef fish surveys (Samoilys and Carlos 2000). Typically this is a downward bias (Ackerman and Bellwood 2000) that can, particularly where rare species are of interest, severely affect the conclusions drawn in a given analysis. In this example for instance, the highest and lowest observed species richness' in Mombasa were observed in subsequent years (1991-1992). Yet it is highly unlikely that there was a true loss of 29 species between those years followed by an increase of 9 species the year following. It is much more likely that low detectability of some of the rarer or more mobile species affected the observed counts across the transects within each year, leading to depressed counts in 1992. In contrast, the occupancy model estimates overlap substantially, indicating that there were likely between 113-121 species present at Mombasa in the early 1990's.

Given the consistent increases in observed species richness across all sites and years, using occupancy models to estimate true richness has substantial potential to reduce sampling error in a given set of data and, as a consequence, to increase the process signal strength that is inherent in the data itself (Allen and Starr 1982). Where, for example, the kinds of year to year variation discussed above are introduced to data through detection heterogeneity among species, the process signal of interest may become substantially weakened. Given that the most important questions for reef ecologists are ecological ones, these kinds of statistical estimators have the potential to structure some portion of sampling error in data,

while also providing ecological quantities of interest such as occupancy. These twin properties of reducing sampling variation and increasing signal strength suggest that occupancy models may see wide application in reef ecology in the near future.

Abstract. Cabo Pulmo is the northernmost coral reef in the eastern Pacific, and has a remarkably high biodiversity. The Mexican government declared the area a National Park in 1995 and protection has been quite effective, resulting in increases in biomass and abundance of predator fish species. This study evaluates changes in average trophic level (indication of carnivory) and community structure of the 13 most important reef fish families, between 1987 to 2006. We performed censuses in observation cylinders (N=230), and calculated several ecological indices, as well as the taxonomic distinctness and average trophic level of the assemblages. The results show that fish community composition clearly differed in time as richness, diversity, evenness and taxonomic distinctness had higher values in the 1990s; at the same time the trophic level increased through the years, and its relation to most ecological indices was inverse and significant. The National Park had a positive influence on the fish community, at the same time carnivores seem to have depleted the abundance of many species and simplified the fish community. We conclude that conservation efforts have reached its goals but at the same time produced unexpected consequences in the composition and function of the area.

Key words: Community structure, Average trophic level, Marine protected area, México, Pacific Ocean

Introduction

The eastern Pacific region has many small and underdeveloped coral reefs, distributed from México to Colombia. The environmental conditions of this region are not adequate for zooxanthellate corals as the area presents relatively cold waters, large sandy tracts, a narrow continental shelf, and intense winter upwellings (Glynn and Ault 2000). However, the importance of those ecosystems in Latin America is high as they are characterized by an unusual mix of endemic taxa and immigrants from the central and western Pacific (Ketchum and Reyes-Bonilla 2001), and thus represent key areas for conservation (Aguilar et al. 2007; TNC 2008).

México is one of the countries that have paid substantial attention to research and protection of reefs, especially in the Gulf of California. In that inner sea there are only two areas where coral development is good enough that they can be considered as "functional reefs": San Gabriel Bay (24°N) and Cabo Pulmo (23°N; Reyes-Bonilla 2003). The latter has been recognized as a hotspot of marine species richness (Steinbeck and Ricketts 1941; Brusca and Thomson 1975; Robinson and Thomson 1992; Reyes-Bonilla 2003; Sagarin et al. 2008); the literature indicates more than 200 fish species and over 500 invertebrates reported for the area (Villarreal Cavazos et al. 2000; Hendrickx et al. 2005). The Mexican government recognized the relevance of the site and declared it a National Park in 1995, but the management plan was published until December 2006. According to the law of the country, all protected areas require at least some portion that should be open to extractive use (this means that the "no take zones" are not supported by the federal government, but nevertheless particulars or fishing cooperatives can exert its right to completely close any part of their own or concession areas; Lubchenco et al. 2007). However, at the same time the law establishes that no human use can be done in a reserve until the management plan is published (Aguilar et al. 2007). As a result of these regulations, we have witnessed the unusual case that *because of the lack* of a conservation program, the Cabo Pulmo residents, who were originally fishermen but changed their way of living to provide diving and sport fishing services, took the unilateral decision to avoid extractive uses in the park, and with help from NGOs and academic institutions, *de facto* managed efficiently the area for over a decade (Arizpe 2005).

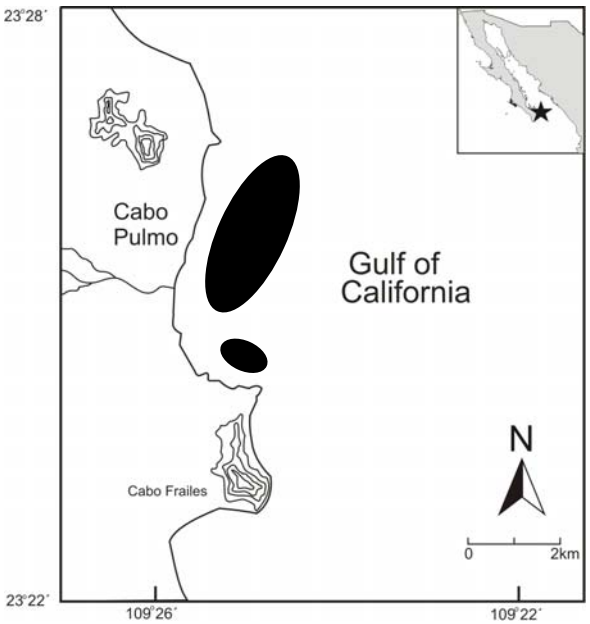

Figure 1: Study area, showing the approximate position of the coral reef.

There is a growing body of scientific evidence pointing out that no take areas bring noticeable advantages for conservation and fisheries, particularly higher biomass and larger fish sizes, an increase in abundance of carnivores (this is, a higher trophic level of the assemblages), and economic benefits for residents (Halpern 2003; Gell and Roberts 2003; Lester and Halpern 2008). Cabo Pulmo National Park is no exception and in the last decade there has been a noteworthy improvement in the general state of the reef and also in the living standard of the people (Angeles-Villa et al. 2008). Considering this background, the objective of this paper was to assess the effects of the conservation of the reef, taking as a measure the changes in trophic level and in several ecological indices of the fish assemblages at Cabo Pulmo. We noticed that as anticipated, a steady increase in abundance and size of carnivores has been occurring after the park was established, but interestingly, this also brought an unexpected reduction in the complexity of community structure. Our results call attention to responses at species and community level which were not anticipated when management efforts focused on specific targets (higher level predators), and resulted in an "ecological surprise" (Doak et al. 2008).

Material and Methods

Study area. Cabo Pulmo reef (Fig. 1) is located in the southeastern portion of the Baja California Peninsula, México. The area has a warm, tropical climate, and the sea temperature yearly fluctuates between 18° and 30° C (Arizpe-Covarrubias 2008). Photosynthetic pigment concentration is only 0.24 mg/m^3, with an annual range of 0.06 to 1.44 (NASA 2008), and correspondingly, nutrient concentrations are among the lowest in the Gulf of California, (WOA05 2008).

The coral community grows on basaltic outcrops and is composed of 12 species of five genera, with *Pocillopora* as the dominant one, followed by *Porites* and *Pavona*. (Alvarez-Filip et al. 2006). Coral cover was high in the 1980s and 1990s (over 30%; Reyes-Bonilla and Calderón-Aguilera 1999; Arizpe 2005) but decreased drastically after the 1997 ENSO event (Reyes-Bonilla 2001). To date recovery has been limited as the reef was impacted by several hurricanes and tropical storms, especially in 2003 (Alvarez-Filip et al. 2006). As a result, the coral cover in 2007 was 21%, a very small step up from the late 1990s.

Field Work. For this study we conducted censuses at Cabo Pulmo in nine different years during the interval 1987 to 2006. The counts were done at depths from 1 to 15 m (base of the reef), inside observation cylinders of 7.5 m radius in 1987 and 1994 (176 m^2 in area), and of 5 m radius in the remainder years (76 m^2). Because of the difference in sampling area and to make adequate comparisons, the number of individuals per census was scaled using density (ind/m^2) before any calculation.

For the analysis we included density data of the 13 "typical" reef fish families: Acanthuridae, Apogonidae, Blennidae, Chatodontidae, Haemulidae, Holocentridae, Labridae, Lutjanidae, Pomacanthidae, Pomacentridae, Scaridae, Scorpaenidae and Serranidae (Bellwood 1998; Robertson 1998), which are also the most abundant at Pulmo reef (Villarreal Cavazos et al. 2000). From that information we calculated the following community indices: species richness (S), Shannon-Wiener diversity (H´), Pielou´s evenness (J´), average taxonomic distinctness (Δ*) and taxonomic distinctness (Δ+). Finally, we estimated the average trophic level of the fish assemblages at each cylinder using the method of Pauly et al. (1998), and information of diet for each species from FishBase (2008).

Statistical analyses. We performed several statistical procedures. First, parametric analysis of variance and Tukey *a posteriori* tests were used to determine differences in each index among years in the sampling span. Then, the Pearson correlation coefficient was applied to evaluate the relation between trophic level and each ecological index, and simple linear regressions were conducted between trophic levels and those indices that were significantly related to the factor; in this case the idea was to depict the rate of change in the community structure using the slope of the regression (Zar 1999).

Results

The analysis of variance evidenced statistical differences in most indices (in all cases, degrees of freedom were 8,221). For richness, the year 1987 (19.8 ± 0.9 sp/census) differed from the rest (10.9 ± 0.8 sp/census general mean from 1994-2006; F=20.1, P< 0.01). In the case of density, again 1987 had the highest figure (2.7 ± 0.7 ind/m^2), but in addition, 2003, 2004, 2005 and 2006 had more individuals per census (in all cases over 1.0 ind/m^2) than years between 1994 and 2001 (less than 0.8 ind/m^2).

Diversity was highest in 1987 (1.77 ± 0.03 decits/ind), but the ANOVA and Tukey test determined that the difference among years was actually caused by the low values observed in 1994, 2002 and 2003, related to the rest (F= 4.1, P= 0.0001). Finally, evenness was significantly lower in 1994, very high in 1999, and remained statistically similar in the remainder years (F= 3.2, P= 0.001).

When the analysis covered taxonomic diversity (Δ+) there were no statistical difference (F= 1.7, P= 0.09) but in contrast, for Δ* (taxonomic distinctness) all years before 2000 had higher values than those of ensuing ones (F= 3.5, P= 0.001). The trophic level also differed among years (F= 3.1, P= 0.002), and 2002 and 2006 showed higher figures than all others (Fig. 2); furthermore, as a group the values of between 1994 and 1999 were significantly lower than those of the 2000s (t 228= 2.18, P= 0.03).

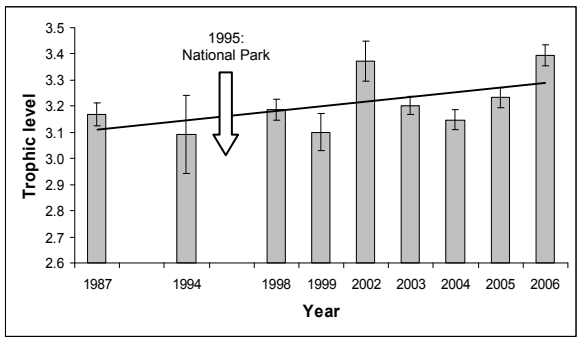

Figure 2. Trophic level of the icthyofauna at Cabo Pulmo reef, western México (average ± SE), and regression line of the values (slope: 0.008, ordinate: -14.65. r^2= 0.15, p= 0.16).

The data (Fig. 2) show that the trophic level has increased steadily from 1994 to 2006 (annual change of 0.008 units, according to the regression slope), and especially after the declaration of the National Park (annual change in 1999-2006 was 0.019); however, in both cases the relation was not significant, indicating that although the change seems to exist it is still not statistically relevant.

The correlation analysis between trophic level and the ecological indices (Table 1, Fig. 4) showed that the latter (including those with a taxonomic component), behaved similarly and were significantly linked. At the same time, it depicted that the trophic level was related negatively with all indicators, except fish density (positive relation) and Δ+ (not significant).

Table 1. Pearson correlation coefficients for ecological indices and trophic level of the reef fish community at Cabo Pulmo reef (1987-2006). All values are significant, except when noted (*). Key: S= species richness; N= density; H´= Shannon-Wiener diversity; J´= Pielou evenness; Δ*= Average taxonomic distinctness; Δ+= Taxonomic distinctness.

	S	N	H´	J´	Δ*	Δ+
N	0.33

The NMDS showed that community changed noticeably between 1987 and the 1990s, but afterwards (between 2003 and 2006), the composition of the assemblages became quite similar to what it was before artisanal fisheries were important.

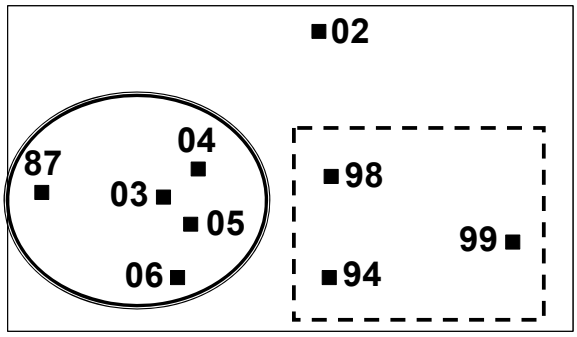

Figure 3. Nonmetric multidimensional scaling plot of the fish assemblages at Cabo Pulmo (1987-2006).

Discussion

This paper shows that as observed elsewhere, the establishment of Cabo Pulmo Marine Park led to fast changes (Polunin and Roberts 1993; Russ and Alcala 2004), and also modifications in the fish community. Practically all ecological indices showed a reduction in value with time (they were especially low in the early years of this decade), while at the same time the average trophic level of the community ascended gradually. These trends were clearly pointed out by the correlation analyses (Table 1) in which practically all coefficients had a negative sign, meaning an inverse relationship.

The effects of the increase in carnivore are better shown in Fig. 4, where simple linear regressions evidenced how a rise in trophic level is followed by a decrease in richness, diversity and taxonomic distinctness of the fish fauna, this is, by a simplification of the general community structure.

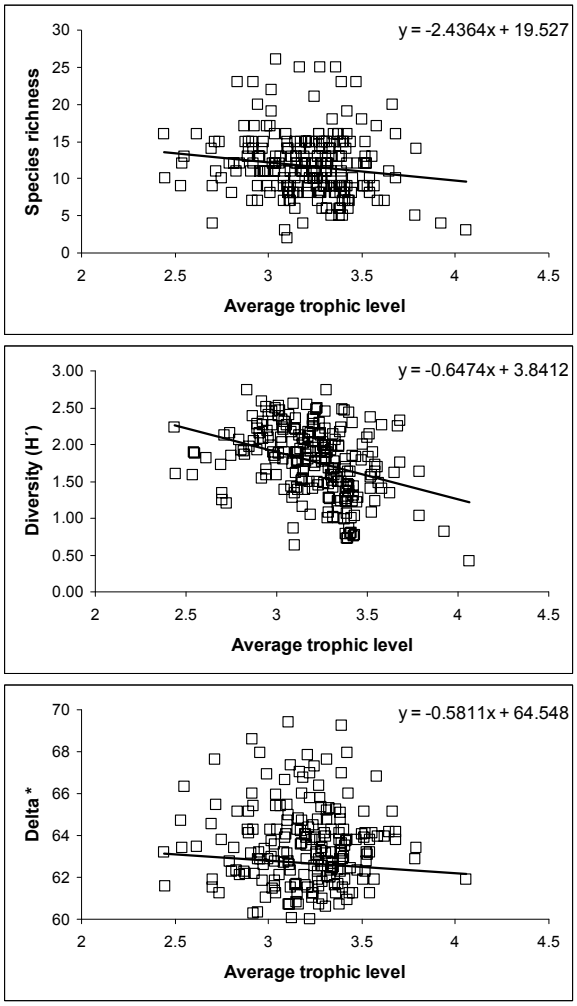

Figure 4. Regression analyses of trophic level and selected ecological indices of the icthyofauna at Cabo Pulmo reef.

Of those indices analyzed in Fig. 4, Shannon-Wiener diversity and species richness were most affected, as shown by the regressions slope. These measures depend on the number of fish taxa seen per transect and the relative abundance of the species (Magurran 2003), and consequently we suggest that the action of predators has been gradually diminishing the variety of fish types, and also the dominance of pomacentrids and labrids, the best-represented families in the reef (Alvarez-Filip and Reyes-Bonilla 2006).

In addition to the increase in trophic level, there are other indications of the good state of the assemblages. For example, the length of commercial species like the bumphead parrotfish *Scarus ghobban* Forskaal 1775, and the leopard groper *Mycteroperca rosacea* (Streets 1877), have augmented in the last years as a consequence of the lack of fishing (Fig. 5). Also, the larger size of fish aggregations is apparent, and finally the sightings of tiger and bull sharks in the reef have become common. All these observations point out the fact that large predators have returned to the reef.

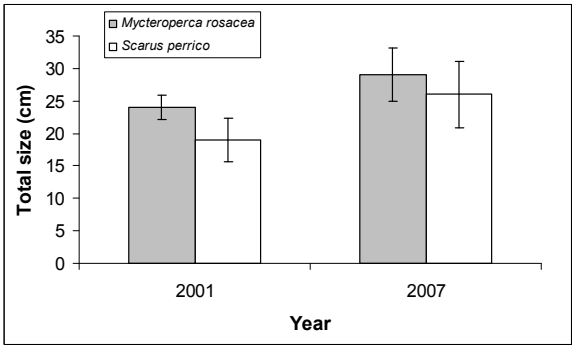

Figure 5. Differential in size (total length) of two key commercial species at Cabo Pulmo reef in the last decade.

The cited changes in fish assemblages are not a response to the local reef condition; to the contrary, coral cover has had small variations in the aftermath of the 1997 ENSO (average from 20% to 23%; Reyes-Bonilla 2001, 2003), especially because of repeated hurricane-caused damage (Alvarez-Filip et al. 2006). In addition, preliminary data shows that other faunas have been also influenced by the presence of higher level fish carnivores; for example, predatory damage is increasing on sea stars, and the abundance of certain species such as the urchin *Diadema mexicanum* Agassiz 1863, in 2006 was much reduced from the one in 1987. We suggest that the increase in fish predators is causing a substantial modification of the composition (and probably the function) of the entire reef ecosystem.

The response of the fish community of Cabo Pulmo to the increase in trophic level coincides with Barrett et al. (2007) remarks that predation is causing species specific and complex responses in Tasmanian reefs; however there is a key difference among regions because richness shifted in opposite directions as a consequence of the presence of large predators (down in México, up in Australia). In short, the divergent results advice of the need of more studies in different geographic realms before the trends of the ichtyofauna can be established with confidence.

We conclude that the establishment of Cabo Pulmo National Park has been a success from the perspective of the increase in abundance of carnivore species and sizes, and in general it can be said that the fish fauna shows an excellent conservation status. However,

there has been a simultaneous decrease in several ecological indices such as richness, diversity and taxonomic distinctness, an evidence of a simplification of the community, probably due to the depletion of specific kind of prey. Undoubtedly the conservation efforts have reached its goal, but nevertheless they brought upon unexpected changes in the ecological complexity and probably diminished the range of functions of reef fishes in this protected area.

Acknowledgements
This paper represents the work of many students and colleagues who has visited Cabo Pulmo with us in almost 20 years of study. In particular we recived funding by SEP-PROMEP (Ref. UABCS-003, to HRB) and CONACYT-SEMARNAT (Ref.2002-C01-0189/A-1, to L Calderón-Aguilera, CICESE, Ensenada). LAF was supported by CONACYT (reg. 171864) and SEP Doctoral scholarships.

Abstract. Hurricane Rita, a category 3 storm, passed within 83 km of the Flower Garden Banks (FGB) on September 23, 2005. Prior to that, in August 2005, Flower Garden Banks National Marine Sanctuary (FGBNMS) staff observed coral bleaching on the reef cap (18-23 m). In November 2005, we assessed hurricane damage and the effects of the bleaching event at the East Flower Garden Bank (EFGB) long-term monitoring site (Aronson et al. 2005). In June 2006, we conducted monitoring which included methods employed in November 2005. Hurricane Rita removed ~1.5% of coral colonies in repetitively photographed quadrats (mostly *Diploria strigosa*, *Porites astreoides*, and *Montastraea* spp.; sizes: 76 to 6,448 cm^2. Monospecific areas of *Madracis mirabilis* experienced catastrophic levels of breakage and toppling. Furthermore, ~10% of coral colonies (mostly *Montastraea annularis* species complex, *M. cavernosa*, and *Millepora alcicornis*) were bleached, an unprecedented bleaching level at the FGB since 1990 when ~5% of corals bleached (Hagman and Gittings 1992). Corals in deeper photo-quadrats (on the reef slope at 32-40 m) exhibited less bleaching than on the reef cap. The passage of Hurricane Rita caused water temperature to drop by 2-3°C, a hiatus in the prolonged thermal stress (> 30°C) which lasted 38 days. In June 2006, reef cap corals had largely recovered from the bleaching event of the previous summer, with bleaching closer to normal levels ~1%, while coral cover values and species relative abundance, remained stable.

Key words: Hurricane Rita, 2005, Gulf of Mexico, coral reef, damage, impact, bleaching, scouring, recovery.

Introduction

Hurricane-force tropical cyclones have frequently entered the Gulf of Mexico and traversed the East and West Flower Garden Banks (EFGB: 27°54'N; 93°35'W; WFGB: 27°52'N; 93°48'W) (Scholten and Deslarzes 1988). During the 20th century, severe hurricanes (Categories 4 and 5 on the Saffir-Simpson Index) may have moved through the FGB region (within ~250 km of the FGB) in 1900, 1909, 1915, 1957, 1961 (Category [Cat] 5), 1964, 1974, 1979, and 1980 (Cat 5). In August of 1980, Hurricane Allen, with a >5-m surge and wind speeds of 96 km/hr, caused physical damage to the coral reefs of the FGB long-term monitoring site (C. Combs, pers. comm., 1990).

The 2005 hurricane season in the Atlantic was the most active to date, fueled by record high sea-surface temperatures. Eleven tropical cyclones entered the Gulf of Mexico in 2005. On September 23 Hurricane Rita passed within 83 km of the FGB as a Cat 3 hurricane (Fig. 1); the other 10 storms passed more than 500 km away (The Weather Underground 2005).

Preliminary assessments of the FGB coral reefs following Hurricane Rita included substantial mechanical impacts, evidence of fractured and displaced corals (one dislodged colony was 4 m across and 2 m in height), sediment-scoured corals bordering large sand flats, and corals gouged and damaged from water-borne projectiles (Fig. 2, 3, 4). Impacts of Hurricane Rita at the FGB were preceded and followed by other natural disturbances: extreme seawater warming from August through November 2005 causing coral bleaching (48% of coral colonies were either partially or totally bleached) and the

offshore transport of river runoff from the Texas-Louisiana coast after the storm (NOAA CoastWatch 2005).

Figure 2: Sediment-scoured corals at the edge of a sand flat at the EFGB in October 2005. The scouring and sand removal were caused by the passage of Hurricane Rita on 23 September 2005. Photo by E. Hickerson, FGBNMS.

Figure 3: Coral colony gouged by waterborne projectiles during Hurricane Rita on 23 September 2005. Photo by E. Hickerson, FGBNMS.

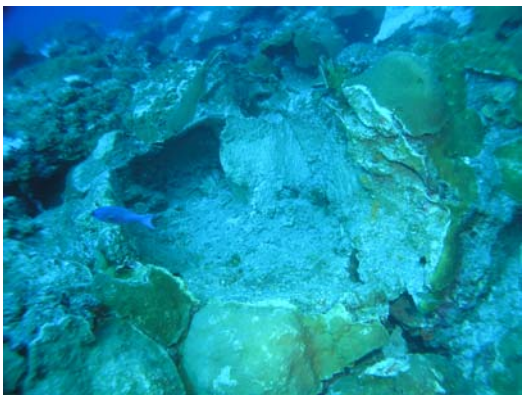

Figure 4: Footprint of a coral colony dislodged from the FGB reef cap by Hurricane Rita on 23 September 2005. Photo by E. Hickerson, FGBNMS.

In order to assess the impacts of both Hurricane Rita and the thermal stress on the benthic community at the EFGB, we made before-and-after comparisons of repetitive photographic quadrats, video footage of monitoring site perimeter lines, and of temperature and salinity data on the reef cap (turbidity, pH, DO, and Photosynthetically Available Radiation [PAR] data were lost to the storm).

Material and Methods

Repetitive Quadrats: To assess changes in the coral assemblage due to Hurricane Rita and bleaching, we photographed repetitive 8-m^2 quadrats within the 100 m x 100 m long-term monitoring site (18-23 m) and associated deep stations (32-40 m) in November 2005 (Gittings et al. 1992). The percent cover of benthic components was analyzed using CPCe® point-count software with Excel extensions (Kohler and Gill 2006) for repetitive photographs taken in June 2005, November 2005, and June 2006. Benthic components assessed included coral species cover, bleaching, paling, concentrated and isolated fish biting, and disease; as well as the cover of macroalgae, turf, and crustose, coralline and bare cover (CTB). We also used planimetry (Sigma Scan Pro 5®) to analyze selected corals within repetitive quadrats between June 2005 and November 2005. The goal of this analysis was to determine whether dominant framework-building corals of the FGB (*Montastraea annularis* species complex, *Diploria strigosa*, and *Colpophyllia natans*) grew or lost tissue laterally and to quantify the amount of coral cover lost due to the storm. Descriptive statistics were used to characterize the effects of Hurricane Rita within 8-m^2 repetitive quadrats.

Perimeter Lines: Perimeter lines around the 100 m x 100 m site were videotaped and a general sense of coral condition was obtained between June and November 2005. Divers videotaped two 100 m segments of the perimeter lines at the East Bank (north and east margins) in November 2005.

Perimeter lines were analyzed for hurricane effects such as toppling, removal, or breakage of coral heads, and thermal stress effects including coral disease, bleaching, paling, isolated and concentrated fish biting. These analyses were qualitative and therefore no statistical analyses were conducted.

Hydrological Data: We used YSI 6600 Series datasonde and a HoboTemp thermograph deployed on EFGB reef cap to examine temperature and salinity (specific conductance) data in June and November 2005. Storm damage done to the sensors prevented us from examining other data (turbidity, pH, DO, and PAR).

Results

Coral cover within repetitive quadrats on the EFGB remained high in November 2005 at approximately 61%, and species relative abundance showed continued stability with *Montastraea annularis* species complex, *Diploria strigosa*, *P. astreoides*, and *M. cavernosa* as the four dominant species (Fig. 5). Approximately 1.5% of coral colonies within repetitive quadrats were missing, most likely due to the effects of Hurricane Rita. This did not noticeably affect coral-cover estimates, which did not vary substantially from June 2005 (Fig. 5). *Diploria strigosa*, *Porites astreoides*, and *Montastraea* spp. comprised the majority of missing coral colonies with sizes ranging from 78 to 6,296 cm^2.

The most noticeable difference in the study site repetitive quadrats photographed at the East Bank in November 2005 compared to June 2005 was the level of bleaching: 9.74% (± 1.07 SE) in November and 0.57% (± 0.18 SE) in June. Most bleaching occurred on colonies of *Montastraea annularis* species complex, *M. cavernosa*, and *Millepora alcicornis*. Paling and fish biting measurements were low at 1.48% or less, and disease was not observed. In June 2006 bleached corals had recovered and bleaching levels were low (0.62% ± 0.24 SE), and little disease was documented consistent with November results.

From June 2005 to November 2005 algae group dominance changed. In June 2005 macroalgae was high at 24%, while crustose coralline and bare cover (CTB) was lower at 10%. After the hurricane, in November 2005 the inverse relationship between macroalgae and CTB was evident, with 24% CTB and 13% macroalgae (mostly turfs <3cm). Macroalgal cover is seasonally influenced and with the passage of Hurricane Rita it is likely that macroalgae were removed from the substratum (except short turfs). In June 2006 macroalgae and CTB were similar in cover (18 and 17% cover respectively), however, crustose coralline algae appeared to be higher in June 2006 (~11%) while the macroalgae group was dominated by *Lobophora lobata* instead of turfs.

Twenty-one coral heads from the 40 quadrats photographed within the 100 m x 100 m study site were removed between June 2005 and November 2005. Measurements of all missing corals were made from the June 2005 photographs to obtain a total area of coral cover loss. A total of ~3 m^2 of coral cover was removed from the 40 quadrats between June 2005 and November 2005; which amounted to a loss of 1.5% of the coral colonies in repetitive quadrats on the EFGB coral cap (18-23 m).

Among the nine reef slope (32-40 m) quadrats photographed in November 2005, 0.5% of coral colonies (2 colonies) were missing. There was also less bleaching (3.1%) compared to the reef cap quadrats. Coral cover remained high (74.5%) on the reef slope, and the dominant corals were *Montastraea annularis* complex, *M. cavernosa*, *Colpophyllia natans*, and *Diploria strigosa*.

Corals along the EFGB study site perimeter lines showed evidence of hurricane impacts, including the dislodgement, loss, or redeposition of entire coral heads as well as breaking of corals, and abrasion on the reef. There was evidence of bleaching and fish biting. Most distressed corals were affected by bleaching (6.4%), with slightly fewer incidences of fish biting (1.2%). As in June 2005, *Montastraea faveolata* and *M. franksi* were the most affected coral species. No evidence of disease was observed in November 2005. Physical damage was observed at several locations along the north perimeter line in November 2005. A partially bleached, dislodged colony of *Montastraea faveolata* was deposited along the perimeter line (Fig. 6). Several colonies of *Diploria strigosa* were either shattered or completely dislodged.

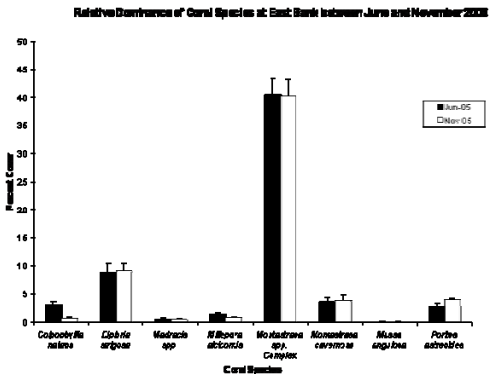

Figure 5: Relative dominance of coral species at EFGB between June and November 2005.

With the passage of Hurricane Rita, there was a sudden drop in temperature on the reef caps of the East and West Flower Garden Banks (Fig. 7). The temperature dropped from 29.6 °C at 0033 hours to 27.4 °C at 1933 hours on 23 September 2005. Temperature rose gradually after the passage of the

hurricane. By 0733 hours on 24 September, the temperature on the reef cap had reached 28.4 °C. During the passage of Hurricane Rita, mean daily salinity at the East Bank was 35.7 NTU.

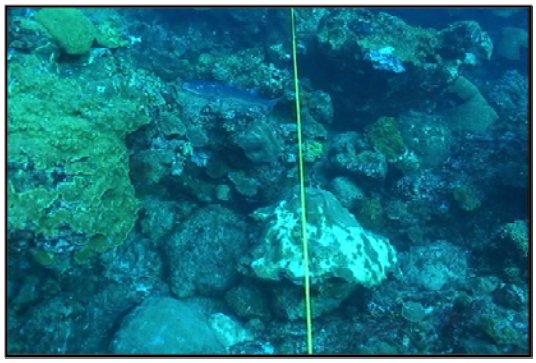

Figure 6: Photographs of a partially bleached *Montastraea faveolata* colony redeposited along the study site perimeter line.

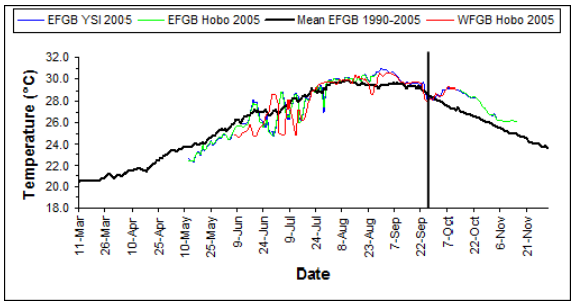

Figure 7: Water temperature at the Flower Garden Banks in 2005 and mean temperature at the EFGB from 1990 to 2005. Water temperature was measured using YSI 6600 Series datasondes (YSI) and HoboTemp recorders (Hobo). A vertical line drawn through the temperature profiles shows the timing of the passage of Hurricane Rita near the FGB (September 23, 2005). The 1990-2005 data are from Gittings et al. 1992, CSA 1996, and Dokken et al. 1999, Dokken et al. 2003, Precht et al. 2006, and Precht et al. 2008a.

Discussion

Mean daily significant wave height at NOAA data buoy 42019 was 4.5 m as Hurricane Rita passed by the EFGB. Depth, measured by the YSI instrument on the EFGB reef cap, rose from 23 to 25 m from 0300 hours on 23 September to 0400 hours on 24 September. The highest point of the storm took place at 2000 hours on September 23 when maximum wave height reached 5.9 m at buoy 42019. The intensity of Hurricane Rita at the FGB was evidenced by physical effects, including the large amounts of sediment removed from sand flats, the dislodgment of corals, and the gouging of corals. Current velocity and direction, measured by current meters placed near the sea surface on Texas Automated Buoy System (TABS) "Buoy V" located near the EFGB, and "Buoy N", located near the WFGB, provide another way to estimate the power of the storm. Buoy N recorded data up until 0830 hours on 23 September; current velocity at that time was 58.09 cm/sec. Current velocity was 57.6 cm/sec at 1100 hours at "Buoy V" (Bender et al., pers. comm., 2005). At the EFGB, water moved in a southeasterly and southerly direction at speeds ranging from 19.7 to 57.9 cm/sec from 23 to 24 September. The current direction recorded at the TABS buoys corroborates our observations at the EFGB of permanent stainless-steel station markers bent in a southerly direction.

In 2005, corals at the FGB were exposed to a prolonged period of thermal stress that was interrupted by the passage of Hurricane Rita. Thermal conditions on the reef cap were unquestionably more severe in 2005 than the average temperature at the FGB recorded to date. The temporary cooling of the reef cap as Hurricane Rita swept through the FGB region was likely the result of the mixing of cold deep water with the warm superficial water (the upper 50 m). At the foot of the FGB (~100 m), seawater temperatures average 19°C. Further down in the water column at 130 m, average water temperature is about 15°C (Nowlin et al. 1998).

Following Hurricane Rita 4 to 6 in of rainfall was recorded along the Mississippi and Atchafalaya rivers on 24 September 2005. Other areas along the coast of Louisiana experienced up to 12 in of rainfall on September 24. Satellite imagery of total suspended matter in the northwestern Gulf of Mexico showed that nearshore water associated with the high levels of precipitation was driven across the shelf and onto the shelf edge, including the area of the FGB. The discolored water seen reaching the FGB could have contained pollutants delivered directly into the northern Gulf of Mexico from industrial sites. Such pollutants include >0.14 km^3/yr of sewage effluent from municipalities, and routine discharges from petroleum refineries and petrochemical plants (Weber et al. 1992) and materials contained in 610 km^3/yr of discharge from the Mississippi and Atchafalaya Rivers (Dai and Trenberth 2002). Coastal and river-borne pollutants may include inorganic nutrients, organic carbon, insecticides and herbicides, and pathogens.

Hurricane Rita affected corals at the EFGB (18-23 m) in a number of ways. Approximately 1.5% of coral colonies photographed at the East Bank were missing from repetitive quadrat stations. *Diploria strigosa*, *Porites astreoides*, and *Montastraea* spp. comprised the majority of missing coral colonies, with sizes ranging from 0.95 to 80.61 cm^2. Approximately 0.5% of coral colonies at the deep stations (32-40 m) were missing. The field of *Madracis mirabilis*, which occurs at a similar depth to the deep stations, suffered severe breakage and damage during Hurricane Rita, but was recovering in June 2006 with new growth extending from the rubble. Corals within the deep

repetitive quadrats are mainly plating morphologies and, therefore, may not be as susceptible to breakage as more fragile, branching morphologies, such as *M. mirabilis* (but see Aronson et al. 1994).

Regional warming in 2005 produced coral bleaching at locations throughout the western Atlantic including Trinidad and Tobago, the BVI, Florida, and the FGB. Sea temperatures at the EFGB were elevated above 30°C, the HotSpot bleaching threshold for the FGB, for 38 days from 30 July to 8 September 2005. Although bleaching events are a natural occurrence, the increased frequency and severity of bleaching events is of concern because the likelihood of bleaching-associated mortality increases with exposure (Hoegh-Guldberg 1999). Additionally, higher temperatures have been linked to increased virulence of marine pathogens implicated in coral diseases (Harvell et al. 2002). We documented unprecedented coral bleaching at the EFGB in November 2005. Repetitive quadrats photographed at that time showed ~10% bleaching of the coral population, a marked increase from June 2005 (Hagman and Gittings 1992). Video perimeter results showed similar bleaching rates and similar differences in relation to video perimeter data taken in June 2005.

Despite the loss of corals, coral cover remained high on the reef cap (61%) and at the deep stations (74.5%). A comparison of shallow study site quadrats with deep station quadrats showed different bleaching patterns and hurricane impacts related to depth. Shallow quadrats had higher levels of bleaching (10%) and experienced a loss of 1.5% of coral colonies. The deep quadrats had lower levels of coral bleaching (~3%) and approximately 0.5% of coral colonies were missing.

The comparison of June 2005 with post-hurricane assessment data collected in November 2005 and June 2006 at the EFGB showed that coral cover within the established long-term monitoring study site remained relatively constant and species relative abundance showed stability with *Montastraea annularis* species complex, *Diploria strigosa*, and *Porites* spp. as the dominant species (Precht et al. 2008). In June 2005 macroalgae was high at 24%, while CTB was lower at 10%. After the hurricane, in November 2005, the inverse relationship between macroalgae and CTB was evident, with 24% CTB and 13% macroalgae (Precht et al. 2008a). By June 2006 macrolagal populations were reestablished while crustose coralline algae increased (Deslarzes et al. unpublished data).

Abstract. Large-scale sampling of stony coral species richness, species distribution, and cover was undertaken at 423 Florida Keys sites between Miami and SW of Key West during 2005 and 2007. A two-stage, stratified random sampling design employed belt transects to enumerate numbers of species and point-intercept surveys to quantify cover. The sampling design incorporated ten reef and hard-bottom habitats from < 1 m to 27 m depth, as well as oceanographic regions and areas inside and outside of protected management zones. These data provide insights into the spatial extent and factors influencing stony coral biodiversity. For stony corals, a pool of ~50 taxa encompassing the Orders Milleporina and Scleractinia, including species and morphotypes, was recorded. Significant differences were found in species richness and cover among cross-shelf habitats, with great values on inner shelf margin patch reefs, followed by deeper fore-reef slope habitats that extended to the 27 m depth limit sampled. In contrast, the shallow fore-reef, especially in areas historically dominated by the branching coral *Acropora palmata*, yielded relatively low numbers of species and cover that are presently dominated by smaller, brooding corals such as *Porites astreoides* and *Favia fragum*.

Key words: Benthic, cover, coral, habitat, species richness, stratified sampling.

Introduction

Coral reefs are in a state of decline worldwide from multiple stressors, including physical impacts, water quality changes, overfishing, disease outbreaks, and climate change (Pandolfi et al. 2003; Bellwood et al. 2004). Coral reefs in a degraded state are often characterized by one or more symptoms, including low abundances of top-level predators, herbivores, and reef-building corals with higher abundances of ahermatypic organisms such as seaweeds (Gardner et al. 2003). Like many coral reef ecosystems, the Florida Keys have experienced symptoms of "degradation" in recent decades, including declines in urchins and corals, particular *Acropora*, that have also occurred in the wider Caribbean (Dustan and Halas 1987; Chiappone et al. 2002). There are also a considerable array of natural phenomena affecting Florida Keys reefs such as atmospheric cold fronts, continental influence (Florida Bay-Atlantic Ocean exchange), and destructive tropical storms. This multitude of stressors makes it challenging to discern the degree to which human activities have comprised ecological integrity relative to natural variability (Somerfield et al. 2008).

Part of the uncertainty in understanding the factors driving decreases in populations of the coral reef ecosystem stems from the quality of the data used to document spatial patterns and temporal changes. Many historical studies lacked the statistical rigor necessary to adequately evaluate changes at the population-scale; in other words, the ecosystem area inhabited by a closed, interbreeding unit (Gardner et al. 2003). Generally, sampling has been at habitat-scales, that is, limited to a few reef sites within particular habitat types in restricted portions of the spatial domain (Dustan and Halas 1987; Porter and Meier 1992; Chiappone and Sullivan 1997). Frequently, selection of sampling sites within a given habitat did not follow standard randomization protocols, and consequently, the derived abundance metrics may not have been representative of the sampled habitats (Murdoch and Aronson 1999).

For the Florida Keys, we contend that the documented temporal changes and current views of spatial distribution and abundance patterns of coral reef benthos, particularly stony corals, are partly biased by the selection of particular reef habitats in particular locations that may not be representative of the larger ecosystem. For example, there is no doubt that areas historically dominated by *Acropora* corals, particularly the shallow (< 6 m) and deeper (8-15 m) fore-reef, have changed substantially, largely due to Caribbean-wide disease events (Dustan and Halas 1987; Chiappone and Sullivan 1997) and bleaching (Somerfield et al. 2008). However, debate has ensued for at least 25 years on the causes of coral reef decline (Porter and Meier 1992; Somerfield et al. 2008), thus making it tenuous for resource managers to determine

which courses of action to take to minimize localized threats in lieu of larger-scale factors such as climate change (Murdoch and Aronson 1999). In this short communication, we report on a large-scale sampling effort that encompassed hundreds of sites across the south Florida shelf to determine patterns of stony coral richness, species distribution, and cover. The 2005 and 2007 surveys were a continuation of previous efforts dating back to 1999 to quantify the abundance and condition of coral reef benthos throughout the FKNMS and built upon pre-existing data from hundreds of sites to guide the sampling design (Miller et al. 2002). Our purpose here is to illustrate the significant spatial variation in stony coral richness and cover, which has implications for reporting "average" reef status and underscores the significant inter-reef variability in this system (Murdoch and Aronson 1999; Somerfield et al. 2008).

Material and Methods

The Florida Keys are an archipelago of limestone islands stretching more than 360 km from near Miami to the Dry Tortugas, representing the only region of extensive reef development in the continental U.S. The islands are part of the south Florida shelf, a submerged Pleistocene platform 6-35 km wide and generally < 12 m deep (Lidz et al. 2003). The primary influences reef distribution and development are paleotopography and fluctuating sea level (Shinn et al. 1989; Lidz et al. 2003). Bedrock throughout the area is Pleistocene limestone, either exposed on the seafloor or lying underneath Holocene reefs and sands (Shinn et al. 1989). From inshore to offshore of the Pleistocene islands, a nearshore rock ledge extends ~2.5 km seaward and consists of hard-bottom, seagrass, and some inshore patch reefs (FDEP 1998). Further seaward is Hawk Channel, a broad trough-like depression dominated by non-coralline, non-oolitic grainstone, but also harboring several thousand patch reefs whose distribution is affected by the number and width of tidal passes (Marszalek et al. 1977). Bands of rock ridges exist further offshore along the outer shelf and on the upper slope from 30-40 m depth before tapering off into the Florida Straits. The semi-continuous reef tract is emergent in places, where Holocene reefs sit atop a Pleistocene coral ridge (~86-78 ka), forming a shelf-margin ledge (Lidz et al. 2003). Coral reef distribution reflects exchange processes between Florida Bay and the Atlantic Ocean (Marszalek et al. 1977; Shinn et al. 1989), which, is related to the size and orientation of the Pleistocene islands, the locations of major tidal passes, and the proximity of the Florida Current to the platform margin (Smith 1994).

At each site, four random sampling points per targeted site were generated in a GIS and located in the field using a differential GPS. Four 15-m transects were deployed per site. For stony coral species richness, an area 0.5-m out from each transect side was searched for the presence of any species present. Along the same transects, coral cover was estimated using the point-intercept method, in which the bottom type every 15 cm along the transect was recorded for a total of 400 points per site.

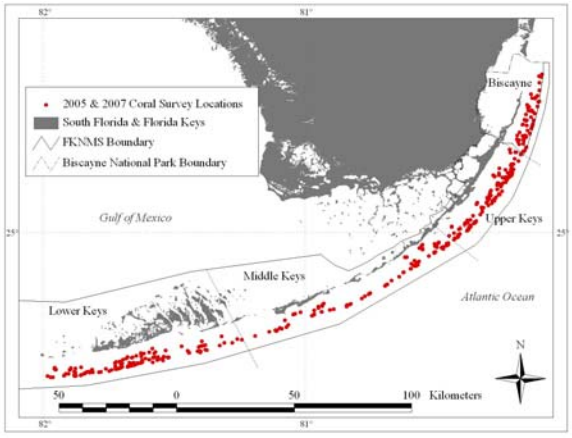

Figure 1: Survey locations sampled for stony coral species richness and cover during 2005 and 2007 in the Florida Keys National Marine Sanctuary and Biscayne National Park.

Table 1: Sampling effort for stony corals in the Florida Keys during 2005 and 2007. Available sites reflect the number of 200 m x 200 m cells with particular habitat based upon FDEP (1998) data

Habitat	Sites (% effort)	Sample area (m^2)	Sites available
Mid-channel patch reef (MPR)	87 (20.6)	5,220	3,532
Offshore patch reef (OPR)	69 (16.3)	4,140	1,243
Inner line spur and groove (IRT)	13 (3.1)	780	87
Shallow hard-bottom (LHBS)	39 (9.2)	2,340	972
High-relief spur and groove (HSG)	70 (16.6)	4,200	238
Patchy hard-bottom (PHBD)	32 (7.6)	1,920	1,247
Deeper hard-bottom (LHBD)	40 (9.5)	2,400	2,395
Low-relief spur and groove (LSG)	47 (11.1)	2,820	1,763
Fore reef 15-20 m (FRS20)	17 (4.0)	1,020	880
Fore reef 22-22 m (FRS27)	9 (2.1)	540	671
Sampling Design Total	423 (100)	25,380	13,028

Statistical estimation procedures for population abundance metrics (proportional transect frequency, cover) for a two-stage stratified random sampling design were adapted from Cochran (1977). Site species richness, species frequency of occurrence, and total coral cover were calculated for each site, and then pooled for sampling strata, consisting of

combinations of habitat, regional location, and management zone factors. Data reported herein emphasize habitat-related patterns. Statistical comparisons among habitats for mean site species richness, species frequency of occurrence, and cover were accomplished by computing confidence intervals (CI) based on the equation: CI = mean ± $t_{[\alpha, df]}$ *standard error. Standard errors were estimated by the two-stage, stratified random sampling design (Cochran 1977) and confidence intervals were adjusted for multiple comparisons using the Bonferroni procedure. The experiment-wise error rate was held at $\alpha = 0.05$ and the comparison-wise error rate was adjusted based on the number of multiple comparisons as follows: comparison-wise error rate = α/c, where $c = k(k-1)/2$ and k = number of categories (e.g. habitat classes).

Table 2: Physical characteristics of stony coral survey sites in the Florida Keys. Values are the ranges in transect depth (m), maximum vertical relief (cm), and site distance from shore (km). See Table 1 for habitat abbreviations

Habitat	Depth (m)	Max. vertical relief (cm)	Shore distance (km)

Results

Surveys of the 423 Florida Keys sites yielded 49 stony coral taxa. Independent of region and management zone, mean (± 1 SE) stony coral site species richness (no. species/60 m^2) ranged from 12.1 ± 0.8 to 19.7 ± 0.4 among the 10 habitats (Table 3). Precision estimates (coefficient of variation) among habitats ranged from 2% to 7%. Stony coral species richness was positively correlated with mean percent coral cover (Pearson correlation coefficient r = 0.630), indicating that sites with greater numbers of coral species tended to yielded higher coral abundance. Among the 10 habitats sampled, maximum transect depth (r = 0.264) and distance from shore (r = 0.469) were only weakly correlated with site species richness, while maximum vertical relief was more highly correlated (r = 0.852). Species richness on mid-channel and offshore patch reefs was significantly greater ($P < 0.002$, Bonferroni-adjusted α) than on shallow (< 6 m), low-relief and high-relief fore-reef habitats. Particularly noteworthy was the low species richness of shallow fore-reef areas historically dominated by *Acropora palmata*. Although patch reefs yielded the highest mean site species richness, there was substantial variability from reef to reef, with species richness among mid-channel and offshore patch reefs ranging from 9-28 and 9-29 species per site, respectively. Deeper (6-15 m and 15-20 m) low-relief spur and groove habitat also yielded significantly greater numbers of species than shallow fore-reef habitats.

Mean stony coral cover ranged from 0.5% to 43.3% among the 423 sites surveyed (Table 3). There was substantial variability both among sites within habitats and among habitats. Mean coral cover was greatest on mid-channel (16.2%) and offshore patch reefs (8.5%), but was less than 8% for all other habitats. Relatively high coral cover on patch reefs was represented by massive framework species such as *Colpophyllia natans*, *Montastraea* spp., *Siderastrea siderea*, and *Stephanocoenia michelini*. Total coral cover was significantly greater on patch reefs ($P < 0.002$, Bonferroni-adjusted α) compared to low-relief low-relief and high-relief habitats on the shallow platform margin, and then increased again on the deeper fore-reef slope, especially below 15-m.

Table 3: Habitat summary of stony coral species richness (no. species per 60 m^2) and cover at 423 Florida Keys sites

Habitat (no. sites)	Richness	Cover
Mid-channel patch reef (87)		
Range	9-28	1.8-43.3
Mean ± 1 SE	19.7 ± 0.4	16.2 ± 1.3
Offshore patch reef (69)		
Range	9-29	0.5-22.5
Mean ± 1 SE	18.8 ± 0.6	8.5 ± 1.2
Inner line reef tract (13)		
Range	7-18	6.0-9.3
Mean ± 1 SE	12.1 ± 0.8	7.0 ± 0.6
Shallow hard-bottom (39)		
Range	8-18	0.8-3.0
Mean ± 1 SE	12.4 ± 0.4	1.6 ± 0.2
High-relief spur and groove (70)		
Range	7-21	0.5-13.8
Mean ± 1 SE	12.4 ± 0.4	5.1 ± 0.7
Patchy hard-bottom (32)		
Range	7-22	0.3-4.5
Mean ± 1 SE	15.2 ± 0.7	1.5 ± 0.3
Deeper hard-bottom (38)		
Range	7-25	0.5-13.0
Mean ± 1 SE	14.8 ± 0.6	2.8 ± 0.6
Low-relief spur and groove (49)		
Range	5-26	0.5-21.0
Mean ± 1 SE	16.1 ± 0.6	3.3 ± 1.2
Fore reef (15-20 m) (17)		
Range	14-24	0.5-21.0
Mean ± 1 SE	18.9 ± 0.7	7.0 ± 4.9
Fore reef (22-27 m) (9)		
Range	13-20	3.0-13.0
Mean ± 1 SE	16.3 ± 0.9	7.2 ± 1.1

Mean proportional transect frequency, or the percentage of transects where species were encountered, allowed for the partitioning of species into rare, common, and very common based upon habitat distribution and frequency of occurrence (Fig. 3). Relatively rare species (e.g. *Acropora palmata*,

Mycetophyllia aliciae, *Mussa angulosa*) were observed in few habitats, and when they did occur, were usually absent on 70+% of transects. Common species, which include many of the framework corals such as *Colpophyllia natans* and *Montastraea faveolata*, were present in most or all habitat types, but exhibited patterns in frequency of occurrence that were strongly habitat dependent (e.g. *C. natans* and *Solenastrea bournoni*). Very common species such as *Porites astreoides* and *Siderastrea siderea* were not only found in all habitat types, but frequency of occurrence values were also very high (> 75%).

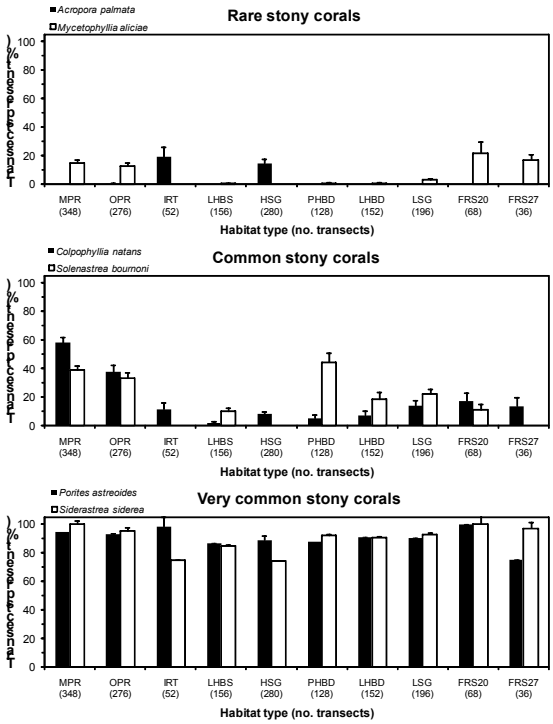

Figure 3: Mean proportional frequency (% of transects recorded) for selected coral species in the Florida Keys, ranging from very common to rare by habitat type. Error bars are +1 SE and numbers in parentheses on the x-axis are the number of 15-m x 4-m transects sampled in each habitat. See Table 1 for habitat abbreviations.

Mid-channel patch reefs were noted for their relatively high coral species richness and cover (Table 3). Figure 4 shows inter-reef variability in these two metrics for 51 mid-channel patch reef sites along ~200 km of the Florida Reef Tract, illustrating reef-to-reef variability, as well as regional variations. For both metrics, coral species richness and cover tended to be greater in the middle and lower Florida Keys, particularly in areas outside of FKNMS no-take zones, relative to the upper Keys and Biscayne National Park.

Discussion

Many biological phenomena are scale dependent, conclusions can be affected by the scale of observation, and caution needs to be exercised in scaling up results from small-scale studies to spatial and temporal patterns that were not sampled (Edmunds and Bruno 1996). Sampling at multiple spatial scales is usually necessary to determine whether patterns at one spatial scale are indicative of regional patterns (Murdoch and Aronson 1999). The interpretation of spatiotemporal changes in community structure is also made complex by biases introduced by site selection. For example, reefs with high coral cover, selected at the start of a monitoring program, can only remain unchanged or deteriorate once monitoring is initiated (Miller et al. 2002).

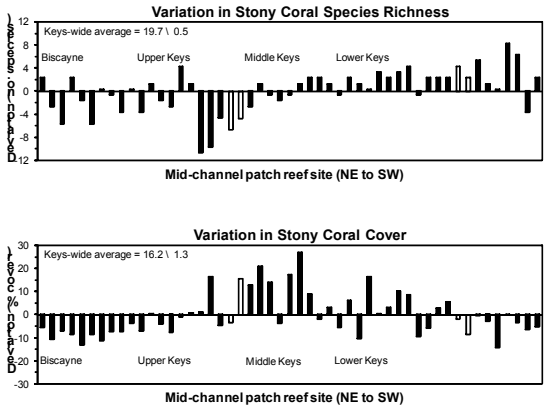

Figure 4: Deviations in stony coral species richness (no. species/60 m^2) (top) and percent coral cover (bottom) from domain-wide averages for Florida Keys mid-channel patch reefs. Open bars are sites within Sanctuary no-take zones.

The patterns and processes governing species richness and community structure are complex and scale-dependent (Murdoch and Aronson 1999. Species richness inventories can emphasize biodiversity hotspots, cold-spots, or the full gradient of species richness values. In addition, there have been attempts to identify indicator species whose occurrence patterns are correlated with the species richness of a larger group of organisms. For our Florida Keys study, taxon richness was measured in terms of the number of stony coral species identified in standardized search areas along belt transects sampled at each site. One of the most significant factors related to species distribution in the Florida Keys is habitat type, which reflects a combination of distance from shore, depth, and geomorphology (i.e. Pleistocene topography) (Shinn et al. 1989; Lidz et al. 2003). Greater numbers of coral species were recorded from inner shelf-margin patch reefs, followed by deeper fore-reef slope habitats that extended to the 27 m depth limit of this study. In other words, the greatest species richness of corals was recorded on either side of the main reef tract, including inner shelf margin patch reefs and offshore

of the main reef tract on the deeper fore-reef slope. In contrast, the shallow fore-reef, especially in areas historically dominated by the branching coral *Acropora palmata*, yielded relatively low numbers of species that are either widely distributed and frequently encountered (*Porites astreoides*) or species that are relatively rare in other habitats.

Relative to species richness, coral cover on Florida Keys reefs was more variable among sites within particular habitats, as well as among habitat types, but exhibited similar cross-shelf patterns to species richness. Coral cover was greater on patch reefs closer to shore and was significantly lower on the shallow platform margin, even on highly structured reefs where live *Acropora* cover was historically more abundant. Massive, mounding coral species dominated coverage inshore and some of these same species are prevalent on the deeper fore-reef, but not on the shallower platform margin. Previous large-scale surveys encompassing a large spatial area (Murdoch and Aronson 1999; Chiappone and Sullivan 1997; Miller et al. 2002) or timeframe (Somerfield et al. 2008) confirm the substantial inter-reef variability in the Florida Keys. Overlain on the geologic history of particular sites (Shinn et al. 1989; Lidz et al. 2003) and along-shelf position (Marszalek et al. 1977) are the responses of individual reefs to disease and bleaching episodes (Somerfield et al. 2008).

Cover and species richness are most frequently used with a focus on corals, because after all, corals are often the dominant organism or they are of high interest to managers. However, when coral cover is regionally low for most habitats as it currently is in the Florida Keys, a broader suite of metrics may be needed to evaluate ecosystem health and condition (Miller et al. 2002). In addition, there are so many potential indirect effects that might result from various management measures (e.g. no-take zones), in addition to larger-scale system variability, none of which can be predicted with any degree of certainty. Many previous and ongoing studies of coral reef community structure in the Florida Keys and elsewhere have focused on benthic cover as the abundance metric of choice for stony corals (e.g. Dustan and Halas 1987; Porter and Meier 1992; Somerfield et al. 2008). Benthic cover represents the net outcome of population dynamic rate processes such as colony recruitment, growth, and survivorship, whereas density and size structure, the two basic components of cover, provide information on the rate processes themselves, as well as on the net outcome. For example, a particular area with high densities of mostly small colonies versus another area with low densities of mostly large colonies may produce similar estimates of stony coral cover, but the two areas reflect very different demographic histories. Spatially explicit estimates of coral population density and size structure not only allow for tracking changes in abundance metrics over time, but can also serve as baseline data for subsequent studies of population and community dynamics (Smith et al. in press).

Abstract. The Southeast (SE) Florida coral reef system is the northern extension of the Florida reef tract. This high latitude system lies offshore a heavily populated and urbanized coast and therefore is affected by numerous environmental and anthropogenic stressors. Using annual monitoring data collected in 2004, the southeast Florida reef community was analyzed to investigate patterns in community composition in various habitat types. Data was collected by SCUBA divers who conducted a $30m^2$ belt transect survey at 24 sample sites offshore Broward County (SE), Florida. Sites ranged in depth range from six to 18 meters. The 24 sites occurred on five different reef habitat categories: ridge-shallow, colonized pavement-shallow, linear inner reef, linear middle reef, and linear outer reef. These sites were established for the Broward County Board of County Commissioners and Environmental Protection and Growth Management Department, Biological Resources Division, in order to monitor Broward County coral communities and sedimentation rates in relation to possible effects from a beach renourishment project. The assessment took place prior to the renourishment project.

Key words: SE Florida, community composition, reef habitats

Introduction

Southeast Florida is comprised of Martin, Palm Beach, Broward, and Miami-Dade Counties. The reefs offshore southeast Florida are the northern portion of the Florida reef tract which ranges from the Dry Tortugas in the south to the St. Lucie Inlet in Martin County to the north. Early studies classified the system into three terraces running parallel to shore (first, second, and third reefs), each separated by sloping sand (Goldberg 1973). Recently, the SE Florida reef system habitats have been characterized in more detail (Moyer et al. 2003; Banks et al. 2007; Walker et al. 2008). From nearshore to offshore, reef habitats include: colonized pavement-shallow, ridge shallow, linear inner reef, linear middle reef, and linear outer reef. These habitats are generally deeper offshore with the colonized pavement-shallow and ridge shallow habitats ranging in depth from approximately 3m to 5m; linear inner reef ranging from approximately 6m to 8m; linear middle reef 12m to 15m; and the linear outer reef 15m to 20m.

Temporal and spatial variations exist in coral reef communities. In Florida Keys National Marine Sanctuary, the Coral Reef Monitoring Project (CREMP) documented stony coral cover declines between 1996-2000 (Callahan et al. 2007). Stony coral species richness was found to be greater on offshore patch reefs (Miller et al. 2002). For southeast Florida, offshore Broward County, species richness and evenness has been shown to increase on a north to south gradient, and *Montastraea cavernosa* was demonstrated to be the dominant scleractinian coral (Moyer et al. 2003). In 1973, Goldberg noted that the second reef (now classified as the linear middle reef) exhibited a greater abundance of gorgonians and stony corals such as *M. cavernosa* and *Dichocoenia stokesii* while the third reef (linear outer reef) had greater abundance and larger colonies of *Meandrina meandrites* and *Agaricia agaricites*. The processes and mechanisms that drive potential differences in community composition throughout the southeast Florida reef system remain unclear (Moyer et al. 2003).

The southeast Florida reef system exists within 3km of the coast offshore a highly urbanized area influenced by numerous impacts from commercial and recreational fishing and diving, major shipping ports, sewer outfalls, canal discharges, ship groundings, and marine construction activities. These reefs are important economic assets with an annual economic input for southeast Florida at over 5.7 billion dollars (Johns et al. 2003, 2004). The uniqueness, proximity, and value require characterization of the community, sustained monitoring, and increased investigations into limiting environmental/ecological processes.

Material and Methods

Data collected in 2004 from 24 sites was analyzed for this study. This year was selected for analysis because this was a period prior to planned beach renourishment dredging and construction activities. These sites were established for the Broward County Board of County Commissioners and the Environmental Protection and Growth Management Department, Biological Resources Division in order to monitor Broward County, Florida (southeast Florida) coral communities and sedimentation rates in relation to possible effects from the beach renourishment (restoration) project (Gilliam et al. 2005).

Each monitored site consisted of a permanent belt quadrat transect. Each transect was 20m long and 1.5m in width for a sample area of $30m^2$. The transects were marked with 21, 45.7cm long and 1.3 cm diameter stainless steel pins fixed in the bottom with marine, two part epoxy or Portland Cement, one meter apart (±1.0cm) in a straight line. The transects were placed in a generally north/south direction. The $30m^2$ transects were assessed by sequentially sampling 0.75 m^2 quadrats along both sides of the transect.

Each stony coral colony (scleractinian and hydrozoan, *Millepora alcicornis*) greater than 2cm diameter in the belt transect was identified (genus and species) and measured (±1.0cm). Two measurements were collected: live tissue length and width and whole colony length and width (which included dead portions and parts of the colony outside of the $30m^2$ belt transect). The number of branching octocorals (excluding *Briareum asbestinum* and *Erythropodium caribaeorum*) and fleshy sponges greater than approximately 2cm in width or height were counted. Community data calculations were: stony coral species density (colonies/m^2), stony coral percent live cover, stony coral whole colony size (cm^2), sponge density (colonies/m^2), and octocoral density (colonies/m^2).

Stony coral, octocoral, and sponge densities were determined by dividing the number of colonies in each transect by $30m^2$. Live tissue area of each stony coral species was determined by applying live tissue length and width measurements to the equation $A = L \times W$ (if $L \neq W$) or $A = \pi(L/2)^2$ (if $L = W$). The sum of all colony surface area values was divided by the entire transect surface area ($30m^2$) to calculate percent live stony coral cover.

Possible relationships among community data and habitat types (treatments) were investigated using multivariate (PrimerE, Clarke and Warwick 2001) and univariate (Statistica 6.0 (Statsoft)) statistical analyses. The sites occurred within five southeast Florida reef system habitat categories: colonized pavement – shallow (n=7 sites), ridge-shallow (n=4 sites), the linear inner reef (n=1 sites), the linear middle reef (n=6 sites) and the linear outer reef (n=6 sites) (Walker et al. 2008).

Community density parameters (three functional groups: stony coral, octocoral, and sponge), stony coral species density, stony coral percent live cover, and stony coral whole colony size (cm^2) data were analyzed. Multivariate analyses were completed on stony coral, octocoral and sponge density as a group along with stony coral species density and percent live cover data to examine differences across habitat categories. Site community data was square root transformed prior to the multivariate analysis and pooled into the five habitat categories (colonized pavement – shallow, ridge-shallow, linear inner reef, linear middle reef, and linear outer reef). Multidimensional scaling plots (MDS) (Clarke and Warwick 2001) were created using a Bray-Curtis Similarity matrix. MDS plots provide a visual representation (a "map") of the similarity (or dissimilarity) between sites such that the distance between sites in these plots is a measure of the relative dissimilarity in community composition. ANOSIM (analysis of similarities) (Clarke and Warwick 2001) tests were used to examine differences in stony coral species and community composition by habitat category. Sample site comparisons with R values of 1.00 indicated that the treatments were completely dissimilar while site comparisons with R values of 0.00 indicated that the treatments were completely similar. SIMPER (similarity percentage breakdown) (Clarke and Warwick 2001) analysis was used to determine which stony coral species or functional group (stony coral, sponge, or octocoral density) was responsible for driving the differences between treatments (habitat categories).

Univariate statistics were performed on the mean whole colony size (cm^2) of three important stony coral species in the system: *M. cavernosa*, *Stephanocoenia intersepta*, and *Siderastrea siderea*. Parametric analysis of variance techniques between habitat categories (ANOVA) and the Student-Newman-Keuls Post Hoc test between means (SNK) were completed after data was log transformed ($\log_{10}[x+1]$). Results were considered significantly different for values of $P < 0.05$.

Results

In 2004, within the 24 sample sites, 31 stony coral species were identified. Overall, the average site stony coral percent live cover was 2.1% ± 3.4% (mean ± SD) and average stony coral density was 2.6 ± 1.2 colonies/m^2. Stony coral cover was particularly high on two sample sites on the colonized pavement-

shallow habitat, FTL4 (16.9%) and FTL5 (14.2%). Octocoral density was 8.9 ± 13.9 colonies/m^2 and sponge density was 12.9 ± 9.4 colonies/m^2. Two of the most common stony coral species were *M. cavernosa* and *S. siderea*. *M. cavernosa* contributed most to overall stony coral cover (Table 1) while *S. siderea* had the greatest density. Table 1 shows *M. cavernosa*, *Porites astreoides*, *S. siderea*, and *S. intersepta* (common species in the area) mean site percent cover and percent of total stony coral cover.

	Mean Site % Cover	SD	% of Total Stony Coral Cover
M. cavernosa	1.7	4.2	53.3
P. astreoides	0.2	0.4	7.4
S. siderea	0.1	0.1	5.1
S. intersepta	0.1	0.1	2.8
Other	0.1	0.4	31.4

Table 1: Mean percent live cover, standard deviation (SD), and percent of total stony coral cover for *M. cavernosa*, *P. astreoides*, *S. siderea*, and *S. intersepta.* Other species include: *A. cervicornis, A. agaricities, Agaricia* spp., *C. natans, D. stokesii, D. clivosa, D. labyrinthiformis, D. strigosa, E. fastigiata, M. decactis, M. meandrites, M. alcicornis, M. faveolata, Mycetophyllia* spp., *O. diffusa, P. americana, P. porites, Scolymia* spp., *S. radians,* and *S. bournoni*.

Fig. 1 shows the MDS plot of community density (the three functional groups: octocoral, sponge, and stony coral) by habitat category. The ridge-shallow habitat was separated from all other habitat categories. This indicated that the ridge-shallow had a dissimilar community composition than the other habitat categories. Bray-Curtis similarity values showed that all sites were 60% similar and the ridge-shallow separated at the 80% level indicating that the ridge-shallow sample sites had more similarities with each other than the other habitat categories.

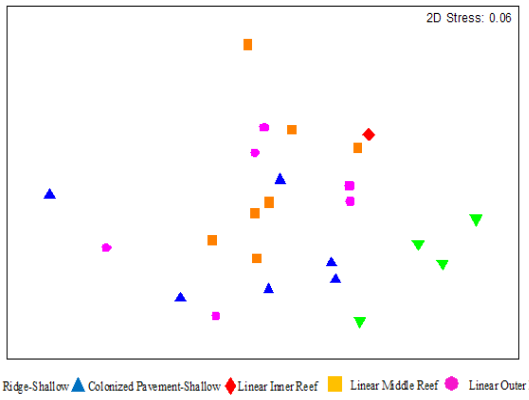

Figure 1: MDS plot of community density by habitat category. Each shape represents community density at one sample site.

ANOSIM results showed that the ridge-shallow community was clearly different but did overlap with the colonized pavement-shallow (R=0.405, p=0.029) and the linear outer reef (R=0.472, p=0.010) communities. The ridge-shallow reef community was well separated from the linear middle reef community (R=0.799, p=0.003). SIMPER results showed that sponge density was the functional group driving the differences (vs. octocoral and stony coral density) between the ridge-shallow and the other habitat categories with lower densities on the ridge-shallow sites (Fig. 2).

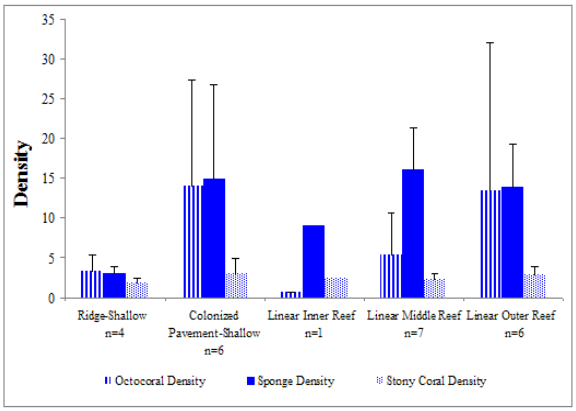

Figure 2: Octocoral, sponge and stony coral density by habitat category. Error bars represent +1 SD (n= the number of sites in each habitat category).

When analyzing each stony coral species percent cover and density in a multivariate manner, the ridge-shallow also had a dissimilar community composition compared to the linear middle and outer reefs. For stony coral percent cover, the ridge-shallow community was clearly different but did overlap with the linear middle reef (R=0.508, p=0.009) and the linear outer reef (R=0.528, p=0.005). SIMPER results showed that *M. cavernosa* was the discriminating species between the ridge-shallow and the linear middle and outer reefs. *M. cavernosa* had more cover on the linear middle and outers reefs compared to the ridge-shallow. *M. cavernosa* also had higher cover on the colonized pavement-shallow due to the two sample sites FTL4 and FTL5, but ANOSIM results did not indicate strong differences with the communities on the other habitat categories (Fig. 3).

For stony coral density, the ridge-shallow community was also clearly different but did overlap with the linear middle (R=0.664, p=0.003) and outer reef (R=0.687, p=0.005) communities. SIMPER analysis showed that the discriminating species in this case was *S. intersepta* because this species was absent on the ridge-shallow sites (Fig. 4). *M. cavernosa* had more colonies on the colonized pavement-shallow due to sample sites FTL4 and FTL5, but ANOSIM results did not indicate strong differences among the communities in the other habitat categories (Fig. 5).

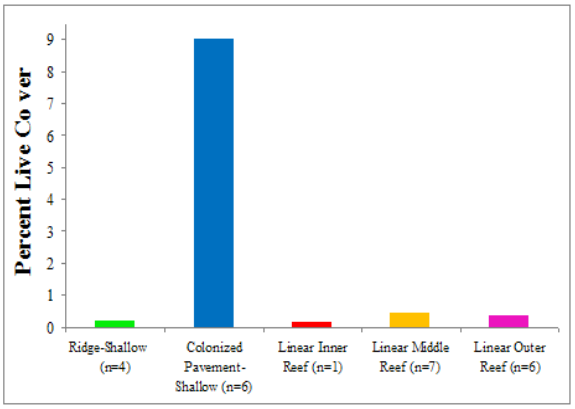

Figure 3: *M. cavernosa* mean percent live cover on all habitat categories. (SDs not shown are: Ridge-Shallow = 0.30, Colonized Pavement-Shallow = 8.02, Linear Middle Reef = 0.70, Linear Outer Reef = 0.23) (n= the number of sites in each habitat category).

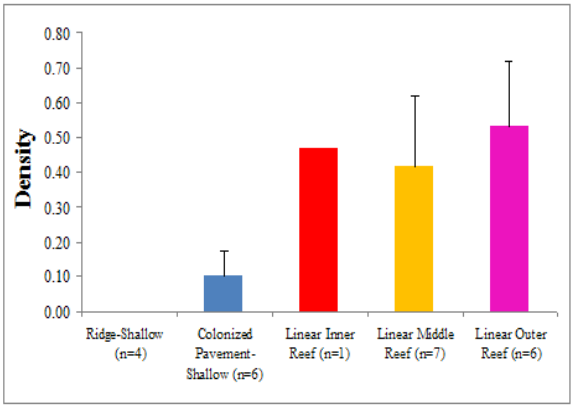

Figure 4: *S. intersepta* mean density for all habitat categories. Error bars represent + 1 SD (n= the number of sites in each habitat category).

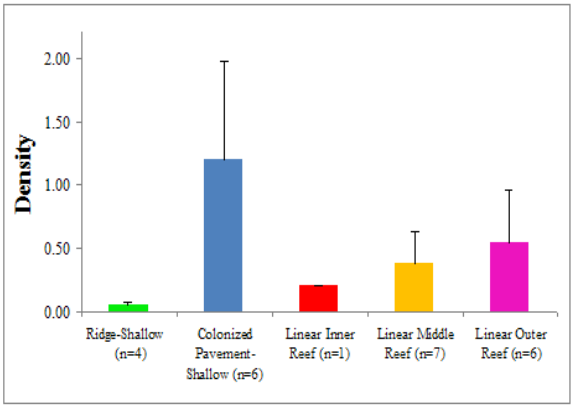

Figure 5: *M. cavernosa* mean density for all habitat categories. Error bars represent + 1 SD (n= the number of sites in each habitat category).

M. cavernosa had significantly larger mean whole colony sizes on the colonized-pavement shallow (Fig. 6). The largest colony in terms of diameter was a *M. cavernosa* colony (150cm) at sample site FTL4. *S. siderea* had significantly larger mean whole colony sizes on the linear inner, middle, and outer reefs and significantly smaller sizes on the ridge-shallow (Fig. 7). *S. intersepta* had significantly larger mean whole colony sizes on the colonized pavement-shallow and the linear outer reef compared to the linear inner and middle reefs (Fig. 8).

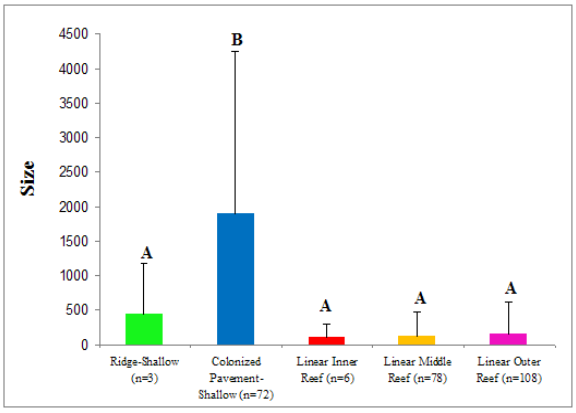

Figure 6: Mean *M. cavernosa* whole colony size (cm^2) for all habitat categories. Error bars represent + 1 SD (n= the number of colonies in each habitat category) (Differing letters indicate a significant difference between habitat categories).

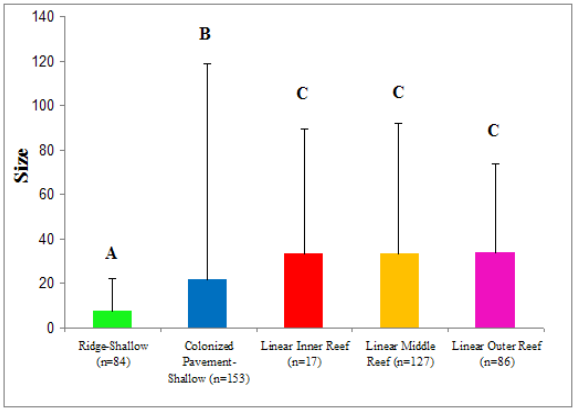

Figure 7: *S. siderea* mean whole colony size (cm^2) for all habitat categories. Error bars represent + 1 SD (n= the number of colonies in each habitat category) (Differing letters indicate a significant difference between habitat categories).

Discussion

The reef system offshore southeast Florida has greater octocoral and sponge densities than stony corals. Stony coral cover is generally less than 3%; however, there are exceptions with several colonized pavement-shallow sites (FTL4 and FTL5) having especially high cover (approximately 15%). The southeast Florida reef community varies by habitat category. With lower sponge densities and stony coral cover, the ridge-shallow has a dissimilar community compared to the linear middle and outer reefs. Three stony coral species (*M. cavernosa*, *S. siderea*, and *S.*

intersepta) are very common and important components of the system. *M. cavernosa* and *S. intersepta* have larger colonies on the colonized pavement-shallow. *S. siderea* have larger colonies on the linear inner, middle, and outer reefs.

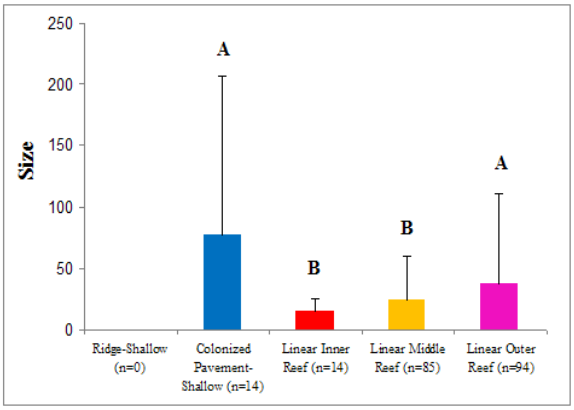

Figure 8: *S. intersepta* mean whole colony size (cm^2) for all habitat categories. Error bars represent + 1 SD (n= the number of colonies in each habitat category) (Differing letters indicate a significant difference between habitat categories).

The ridge-shallow and the colonized pavement-shallow habitats are part of a Ridge Complex that extends from Hillsboro Inlet (Broward County) south to Miami-Dade County (Banks et al. 2007). This complex is made up of sediments from cemented beaches and nearshore deposits (Banks et al. 2007). The linear reefs are made up of a Holocene *Acropora* framework (Lighty 1977; Lighty et al. 1978). According to this study, the inshore (ridge-shallow and colonized pavement-shallow) communities occurring on the cemented beach sand communities are dissimilar to those reef communities occurring on the Holocene *Acropora* framework (linear inner, middle, and outer reefs). The inshore communities are also more likely to be subjected to stress from re-suspension of beach sediments due to wave energy. It is unclear why the two sample sites on the colonized pavement-shallow, FTL4 and FTL5, have such high stony coral cover. Perhaps as Moyer et al. (2003) hypothesized, underlying substrate influences reef community composition. A complete understanding of the reef resources in SE Florida and what influences these vital communities is important for optimal management of a system that is subjected to so many stressors.

Abstract. Organisms associated with live scleractinian corals were studied on four sites located around Hoga and Kaledupa islands in the Wakatobi Marine National Park. The number of coral colonies infested by coral associates was estimated along 20 m long line intercept transects and the number of coral associates found on each coral colony was recorded. A 0.5 m point intercept transect method was used to describe the benthic cover. A total of 2815 associates were recorded infesting 376 coral colonies. The most conspicuous coral associates were lithophagid bivalves making up for 73% of total coral infestations. The highest number of infested colonies was found for the genera *Montipora*, *Pavona* and *Porites*. They represented 33%, 23% and 18% of the total number of colonies infested respectively. The number of infested coral colonies and the density of *Lithophaga* spp. were high in the most impacted site (Sampela) and one of the intermediately impacted site (Pak Kasim's) whereas they were low in the most pristine site (Kaledupa). Despite the high biotic cover of Pak Kasim's, this site suffers from a similar level of infestation as Sampela suggesting process of reef degradation previously experienced by the most impacted site. Our results suggest that coral associates can be used as indicators of coral reef status.

Key words: Coral, Macrobioeroders, Coral predators, Reef health, Indonesia

Introduction

Coral reefs are critically important for the ecosystem goods and services they provide to maritime and subtropical nations (Moberg & Folke 1999). Reefs are currently in serious decline (Bellwood et al. 2004) due primarily to over-harvesting (Jackson et al. 2001), pollution (McCulloch et al. 2003), disease (Harvell et al. 2002), and climate change (Wilkinson 2004; Hughes et al. 2003). Already 20% of the coral reefs have been destroyed (Wilkinson 2004) and show no immediate prospects of recovery, 24% are under imminent risk of collapse through human pressures and a further 26% are under a long-term threat of collapse. The worst scenarios, prospected by Woolridge et al. (2005), suggest that reefs will become devoid of significant coral cover and associated biodiversity by 2050. The managing and a strong focus of key functional groups have become today a priority as part of insurance for sustainability (Hughes et al. 2003).

Coral associates (bioeroder and coral predator organisms) represent one of these key groups. Bioerosion and predation on scleractinian corals are indeed an important part of coral reefs dynamics. Scleractinian corals provide microhabitats and are used by a large number of parasites and other associated organisms, which use the tissue and skeleton of the coral colonies as food or substrata (Frank et al. 1995; Floros et al. 2005). Many taxa are involved and most of these coral associates stress the coral to some degree. Any natural or anthropogenic disturbances that lead to the loss of live coral tissue will ultimately increase the chances of bioeroder invasion. The bioerosion process can lead to important coral damage and even, depending on the intensity, can lead to mortality of coral colonies (Kleemann 2001). Bioerosion plays an important part in the degradation of the reefs and affects coral reef health**.** Nevertheless, although very important, the community structure of organisms involved in this process is relatively poorly documented. The aim of this study was therefore to link the different assemblages of coral associates on reefs around Hoga and Kaledupa islands in Indonesia with the health of these reefs.

Study sites and methods

This study was conducted on the reefs around the islands of Hoga and Kaledupa in the Tukang Besi Archipelago of the south-eastern coast of Sulawesi in the Banda Sea, in Indonesia and took place in July and August 2005. Four sites were studied (Fig. 1) and

were selected with a gradient of degradation (Table 1).

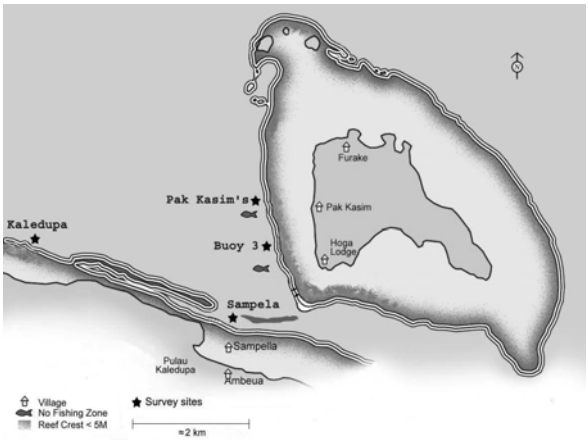

Figure 1: Location of the survey sites.

The number of coral colonies infested by coral associates was estimated along a 20 m long Line Intercept Transect (LIT) (English et al., 1997) at two different depths (6m and 12m). The number of macrobioeroders and coral predators found on each coral colony on the transect was recorded and corals were identified to the most precise level. To link the assemblages of coral associates observed with the characteristics of the benthic habitats, the cover of the major functional groups was estimated using a 0.5 m Point Intercept Transect (PIT) method (English et al. 1997) on the same 20 m-long transect as the macroinvertebrate survey.

Table 1: GPS position and characteristics of the different sites (* means that the difference with the other sites is signifiant, $p<0.01$).

Statistical analyses were performed with Minitab for parametrical and non-parametrical statistics. PRIMER v6 (Plymouth Marine Laboratory, Clarke & Warwick 2001) was used for analysis of community. Cochran tests were used to test for homogeneity of variances before ANOVA. Turkey's pairwise comparisons were used for post hoc comparisons. ANOSIM were performed to analyse similarities between sites after the ordinations (Multidimensional Scaling, MDS).

Results

A total of 831 scleractinian coral colonies belonging to 39 genera were recorded and analysed on 25 transects. Within live corals a total of 2815 associates were recorded infesting 376 coral colonies. The most conspicuous coral associates were lithophagid bivalves (2062 individuals infesting 242 coral colonies) making up for 73% of total coral infestations ; followed by dwelling hermit crabs of the genus *Paguritta* (306 individuals infesting 113 coral colonies) with 10.9% and the vermetid snail *Dendropoma maxima* (242 individuals infesting 116 coral colonies) with 8.6 % (Fig. 2 a and b). Other associates were less common and contributed little to total coral infestations (less than 3%).

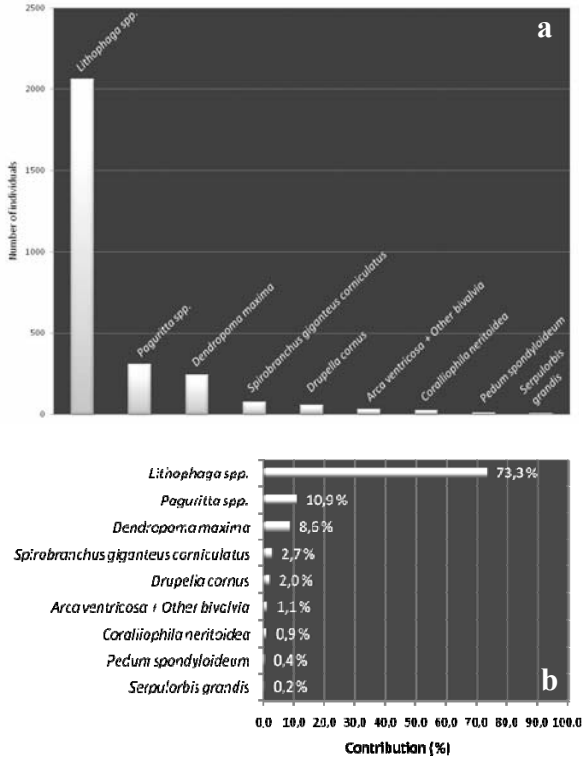

Figure 2: a. Number of bioeroder and coral predator organisms recorded during this study b. Repartition of the different bioeroder and coral predator species.

Infestation rate by scleractinian coral genus

The highest number of infested colonies on the transects was found for the genera *Montipora*, *Pavona* and *Porites* (Fig. 3a). They represented 33%, 23% and 18% of the total number of colonies infested respectively (Fig. 3b). These genera corresponded also with the most common taxonomic groups of scleractinian corals found on the transects (Fig. 3c).

The other genera were less common on the transects (Fig. 3c) and they represented less than 10% of the total number of infested colonies (Fig. 3b).

Infestation by site

At two sites, Pak Kasim's and Sampela, more than half of the coral colonies were infested (54% and 52% of the colonies for the two sites respectively). Only 32% of the coral colonies were infested in Kaledupa. Buoy 3 was in an intermediate state with 44% of the coral colonies being infested.

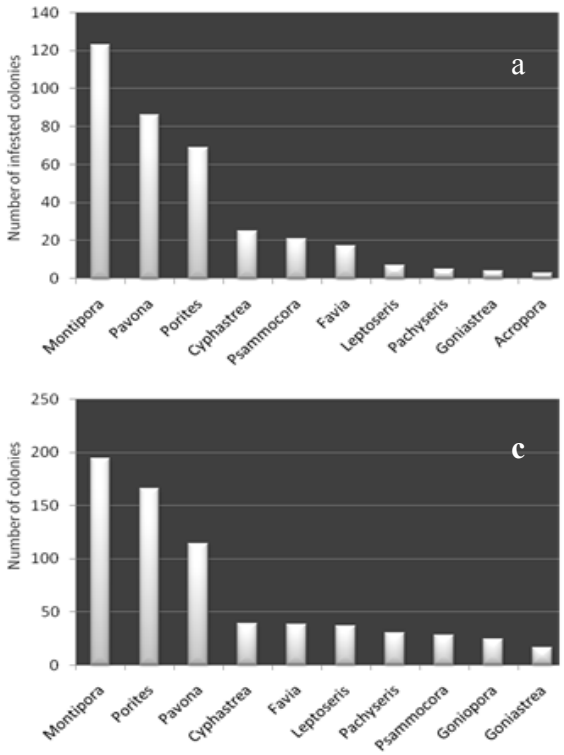
The majority of coral associates was found at all the sites excepted for *Drupella cornus* and *Serpulorbis grandis* which were absent at Buoy 3 and Sampela respectively. Within the same site, no significant difference was found between the two chosen depths (6 and 12 meters) in terms of the total number of infested colonies and the distribution of the studied organisms. A highly significant difference between locations (ANOVA One-Way, $F=18.42$, $p<0.01$) was noticed only for the lithophagid bivalves. The distributions of these organisms in Sampela and Pak Kasim's were significantly different from those in the other sites (Tukey's pairwise comparisons).

Community analysis.

Comparison of coral associates communities by Non-metric Multidimensional Scaling (MDS) and analysis of similarity (ANOSIM) indicated a significant difference among sites (ANOSIM One-way, Global R = 0.691, p=0.001)

Examination of the MDS plot (Fig. 4) showed a tendency of differentiation between the sites. Furthermore, pairwise comparisons of sites from ANOSIM resulted in R-values indicating important differences between Pak Kasim's / Kaledupa, Sampela / Kaledupa, Sampela / Buoy 3 (with R-values > 0.9) and between Pak Kasim's / Buoy 3 (R value > 0.8). No difference was found between the other paired sites. However, with regards to their positions on the MDS plot, the stations seem to be positioned along a gradient between two sites: Kaledupa and Sampela. Two groups were distinct on the MDS, the first one constituted by transects belonging to Sampela and Pak Kasim's, and the second one constituted by transects from Buoy 3 and Kaledupa.

Plotting the densities of the lithophagid bivalves on the MDS (Fig. 4), the global position of the replicates seems to be explained with regards to it. The site considered as the most "pristine", Kaledupa, has the lowest density of *Lithophaga* spp. (all densities < 1 ind.colony^{-1}). At the opposite, separated by the greatest distances on the MDS, are the replicates representing Sampela and Pak Kasim's. The Lithophagid'densities at these sites are the highest. The pattern observed, when the densities of this bivalve on the MDS are superposed, seems to be



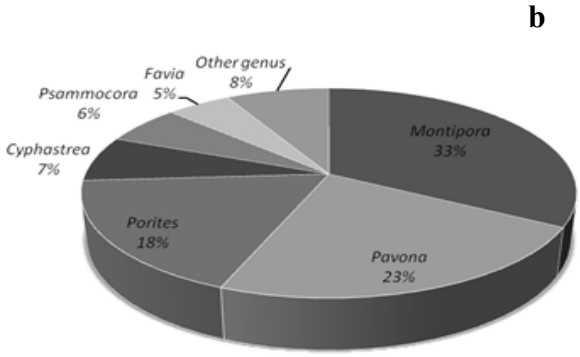


Figure 3: a. Number of scleractinian coral colonies infested for the ten most infected genera b. Ratio of the number of colonies infested corresponding to a given genus on the total number of infested colonies c. Number of colonies for the ten most common scleractinian coral genera.

coherent to the trend of the potential gradient between Sampela and Kaledupa.

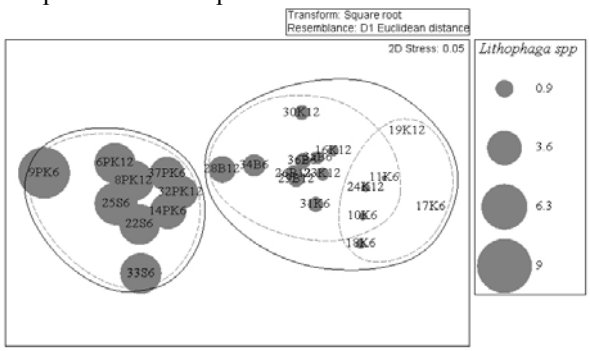

Figure 4: Bubble plot superposing the densities of *Lithophaga* spp. on the MDS (ind.coral colony^{-1}) (codes displayed on the MDS represent the name of transects and their characteristics: transect reference – localisation PK: Pak Kasim's, K: Kaledupa, S: Sampela, B: Buoy 3 – depth of the transect (6 or 12 meters)).

Link with coral reef status.

Significant differences between the studied sites were observed concerning the total benthic cover (multiple Kruskall Wallis tests on the different categories). Percent covers of abiotic and biotic categories in the four studied sites are illustrated in Fig. 5. For the same site, no significant difference concerning scleractinian coral cover was found between different depths. In contrary, for the same depth, significant differences were observed between the sites. The highest biotic (83%) and scleractinian coral cover (43%) was observed at Pak Kasim's. The same level of biotic cover was noticed at Kaledupa and Buoy 3 and no significant difference was observed between the three sites. However, the biotic cover was predominantly composed of soft corals at Kaledupa which explained a relatively low scleractinian coral cover in comparison with the other sites (20% and 26% at 6 and 12 meters respectively). Thus, the proportion of soft corals was significantly higher at this site. At 6 meter depth, the scleractinian coral cover at Kaledupa was significantly lower than that at Sampela (Kruskall Wallis test, $p<0.01$), despite the fact that Sampela was the site for which the biotic cover was the less dominant (only 39% of biotic cover). Abiotic cover at Sampela was thus significantly more important (Kruskall Wallis test, $p<0.01$). Moreover, concerning Sampela, the results of the LIT used for the infestation (126 colonies for three transects) put this site at the same level than Buoy 3 and Pak Kasim's (respectively 242 and 260 colonies for six transects) for the number of colonies recorded. The difference observed in the coral cover between Sampela and the other sites is attributable to the occurrence of a high numbers of small colonies at this place.

Regarding coral growth forms, multiple non parametric Kruskall Wallis tests showed that Kaledupa and Pak Kasim's had a higher proportion of branching corals. No significant difference was observed between the sites for the other categories of lifeforms taken into consideration (encrusting,

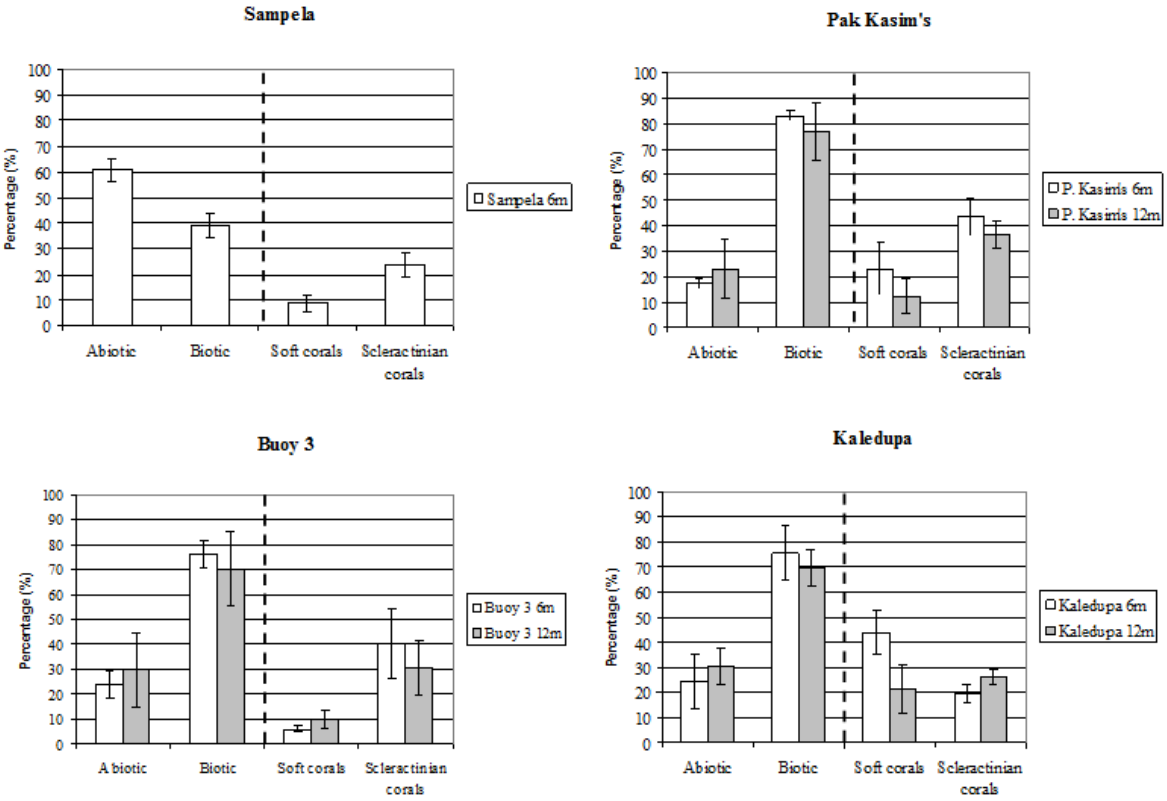

Figure 5: Summary of the benthic cover in the 4 studied sites (Sampela, Pak Kasim's, Buoy 3 and Kaledupa).

massive and foliose corals).

Discussion

When taking into account the environmental parameters measured such as sedimentation rate and rugosity, the obtained results suggest that Sampela can be considered as an impacted site, which agrees with the previous results of Crabbe and Smith (2002). In contrary, the sedimentation rate at Kaledupa was slighthy lower and reef complexity was higher than at the other sites. This site can be considered as a pristine one. The two other sites, Buoy 3 and Pak Kasim's, can be considered to be intermediately impacted.

Analysis of bioeroder and coral predator communities showed that despite the lack of any significant difference in biotic cover between the three sites Kaledupa, Buoy 3 and Pak Kasim's, a common gradient seems to emerge. The superposition of bioeroders' densities on the MDS plot showed the essential role played by the boring lithophagid bivalves, which probably contributes to the similarity between Sampela and Pak Kasim's. Although the biotic and coral cover of Pak Kasim's is high, this site also suffers from a similar level of infestation and perturbation as Sampela. However, unlike Sampela, visual observations and monitoring methods at Pak Kasim's did not reveal a substantial number of dead corals infested by bioeroders as in Sampela. It suggests that this site is going through the process of reef degradation previously experienced at Sampela.

The study of organisms associated with live scleractinian corals in the Wakatobi Marine National Park has shown that infestation rate of coral colonies by coral associates (essentially boring lithophagid bivalves) seems to be related to coral reef status (pristine, intermediate and impacted sites). The infestation rate by coral associates is more important in impacted site than in pristine site. Almost all coral associates are filter-feeding heterotrophs and hence, would be expected to increase in numbers in water with elevated nutrient concentrations (Risk et al. 2001; Floros et al. 2005). In consequence, as suggested by Risk et al. (2001) the health of a reef may be evaluated by scouring the density of coral associates on massive corals. This is base on the theory that coral associate numbers will increase with organic loading: stressed corals will be less able to protect themselves from settlement and overgrowth (Risk et al., 1993).

Abstract. We estimated 673 km^2 of potential habitat for *Acropora palmata* in Puerto Rico using GIS and measured the distribution, abundance and condition with a random sampling approach at six sites (3 east and 3 west coast MPAs). Average density ranged from 0.2 to 9.8 colonies/100m^2 and was highest on west coast sites (Rincón and Cabo Rojo) and these sites showed lower predatory snail (*Coralliophila abbreviata*) prevalence and density. Overall, the prevalence of white band disease was low (2.4% of colonies) yet variable and recent mortality due to diseases was highest in Culebra. Mortality caused by boring sponges (*Cliona tenuis*) was only observed at west coast sites. Nine plots were established in 2007 for long-term monitoring of demographic variables using individually tagged colonies. The results indicate that spatial variability must be considered when assessing trends at the regional level in order to clearly understand population status and responses to management actions.

Key words: Puerto Rico, *Acropora palmata*, spatial distribution

Introduction

In 2006, the corals *Acropora palmata* and *A. cervicornis* were listed as threatened species under the US Endangered Species Act (NOAA 2006), underscoring the need for assessment of status and recovery of their populations. An important realization during the assessment and listing process was that trends in the populations of Puerto Rico and demographic information necessary for modeling changes at the population level was unavailable.

In Puerto Rico the spatial extent of Elkhorn coral (*A. palmata*) and its condition throughout the archipelago was described by Almy and Carrión (1963) and Goenaga and Cintrón (1979) who reported most of the shallow reefs surrounding the island as dominated by *A. palmata*. A few sites described by Goenaga and Cintrón (1979) have been studied over time in Culebra, Fajardo, Guánica, Mona Island and La Parguera, yet no comprehensive monitoring directed towards this species is currently in place. In order to assess *A. palmata* population status this study examines the distribution at large spatial scales combined with localized demographic surveys to determine coral colony condition and existing threats.

Puerto Rico contains the greatest extent of Elkhorn coral in the US Caribbean. The main island of Puerto Rico has been identified as within the genetic population of the eastern Caribbean while Mona Island has been proposed as a mixing zone for the eastern and western populations for the species (Baums et al. 2005). This makes the area an important region to understand population dynamics and provide data towards evaluating recovery of the species.

The goal of this project was to determine the current distribution and condition of Elkhorn coral in Puerto Rico, to provide a basis to assess population status and trends in the archipelago. The first objective was an island wide calculation of the potential habitat for the species. Secondly, a subset of the area was sampled in order to determine the presence and condition of *A. palmata.* Finally, long-term demographic monitoring was initiated utilizing permanent plots.

Materials and Methods

A geographical information system (GIS) was used to create a spatial database in order to delineate the potential habitat of Elkhorn coral around all Puerto Rico. Potential habitat for Elkhorn coral was defined as the areas where occurrence of the species is possible, namely areas of hard substratum to 15m depth. Bathymetric and benthic habitat (NOAA 2001) layers were used to select

areas between 1 and 15m of hard-bottom habitat. These areas were stratified by depth into high probability of encountering Elkhorn in shallowest depths (0-5 m), medium probability in mid depths (5-10 m) and low probability in deeper regions (10-15 m). All map calculations were conducted at 50m cell size. Benthic habitat maps were used to extract areas of unconsolidated sediments and submerged aquatic vegetation. Some areas of habitat classified as 'unknown' due to low water clarity in the aerial photos were included if they were located in areas of suitable depths.

In order to quantify Elkhorn abundance, areas of potential habitat with a high probability of encountering Elkhorn coral were chosen within 6 marine protected areas (MPA) on the east and west coast of the island. The study focused on these MPAs because of their importance to coral reef conservation and to provide an island-wide perspective, although they may not represent all areas of potential habitat. Arrecifes de la Cordillera Natural Reserve (NR) is located off of Fajardo on the northeastern coast of Puerto Rico and includes multiple cays and reefs, while Canal Luis Peña NR in Culebra and Bahías Bioluminiscentes de Vieques NR are located along the eastern coast. Tres Palmas Marine Reserve (MR) in Rincón and Punta Guaniquilla NR in Cabo Rojo are on the main island's western coast, while Arrecifes de Tourmaline NR is part of an offshore reef system located 9.5 km west of Puerto Real, Cabo Rojo.

Within the potential habitat (high probability, <5m depth hardbottom) of each MPA randomly chosen points were selected in GIS (ArcMap 9.1 and Hawth Tools extension) and uploaded to a handheld GPS. In the field a leaded line with surface buoy was used to mark the randomly chosen point to center the $100m^2$ survey area. At each survey area the presence of *A. palmata* and dead standing skeletons within the $100m^2$ was noted by delimiting the area with a floating line (5.6m) used as radius of the circular plot. When live *A. palmata* were present the number, size (maximum length, width and height) and percent live coral cover of each colony was measured for those colonies with their center within the survey area. Colonies less than 50 cm in minimum length were not quantified in these surveys. A Live Area Index (LAI) was calculated (length*width*% live/100) for each colony as an estimate of total coral tissue. Elkhorn colony measures were compared between sites with non-parametric statistical methods. In addition, colony condition variables were assessed including bleaching, disease and predation by invertebrates.

Data on the distribution and condition of *A. palmata* were then used to establish permanent long-term demographic monitoring stations following the protocol of Williams et al. (2006). These sites have been sampled semi-annually since October 2007. All colonies within a $150m^2$ circular plot were measured, photographed, and 12 randomly chosen colonies were permanently tagged for long-term monitoring to quantify their survivorship, growth and changes in condition. At three MPA sites three circular plots (150 m^2) were established with permanent markers.

A size frequency distribution based on classes determined by amount of live tissue was used to show population structure patterns. Colonies between 60 cm^2 and 1,600 cm^2 have low-reproductive potential, while colonies below 15–60 cm^2 are not reproductively active (Soong and Lang 1992). Based on these estimates, large (presumably adult) colonies were considered to be those larger than reproductive size (1,600 cm^2), medium those below minimum reproductive size (50–1,600 cm^2), and small those not expected to reproduce (<50 cm^2). The LAI of tagged colonies per plot was compared between baseline and month 6.

Results

The island-wide potential habitat for Elkhorn coral was estimated at 673 km^2 (67,354 ha). This was classified into areas of high (16% of total area), medium (30%) and low (54%) probability of encountering the species. The area of potential habitat with the highest probability of finding Elkhorn coral was 106.5 km^2 (10,651 ha). The proportion of high probability potential habitat area in the 6 MPAs varied inversely to total MPA size (Table 1).

Table 1: Sampling areas in MPAs on the east and west coast of Puerto Rico and the percent of submerged area (Area) which is considered potential habitat (high probability) for *A. palmata* within each MPA

	Marine Protected Area	Area (ha)	% Potential Habitat
WEST	Tres Palmas (**TP**)	83	62.4
	Arrecifes Tourmaline (**AT**)	7,269	1.3
	Punta Guaniquilla (**PG**)	1,947	2.7
EAST	Arrecifes de la Cordillera (**AC**)	10,082	2.5
	Canal Luis Peña (**CLP**)	633	12.6
	Bahías Bioluminiscentes de Vieques (**BB**)	7,962	1

Elkhorn density and colony measurements were conducted at 431 randomly selected survey areas within the high probability potential habitat of 6 MPAs from December 2006 through October 2007. Overall 30.7% of all points sampled had live *A.*

palmata colonies, yet this varied from 4% at Punta Guaniquilla NR to 73% at Arrecifes de Tourmaline NR showing significant differences in the distribution of live *A. palmata* (Fig. 1). Overall 13.7% of points sampled had *A. palmata* dead standing skeletons or rubble indicating the species used to occur in these areas. This also varied greatly from 0% at Tres Palmas MR to 42% in Arrecifes de la Cordillera NR. Colonies were absent in 27.5% of all points, ranging from 13% at Arrecifes de Tourmaline to 50% at Arrecifes de la Cordillera. Areas where *A. palmata* was absent were gorgonian dominated hard-bottom or uncolonized pavement with sand.

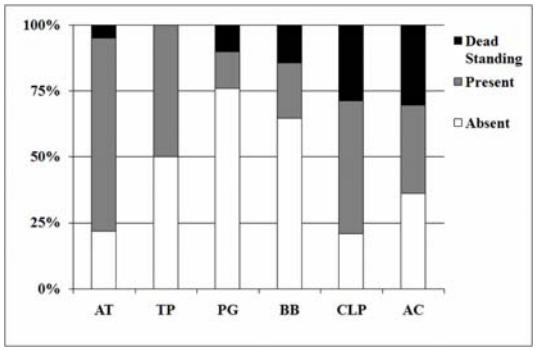

Figure 1: Presence of Elkhorn coral within the high probability potential habitat areas of: **AT** = Arrecifes de Tourmaline (N=60), **TP** = Tres Palmas (N=56), **PG** = Punta Guaniquilla (N=29), **BB** = Bahias Bioluminiscentes de Vieques (N=48), **CLP** = Canal Luis Peña (N=100) and **AC** = Arrecifes de la Cordillera (N=138).

Colony density varied greatly and ranged between 0 and 52 colonies/100m^2. The greatest abundance of *A. palmata* was observed at two west coast MPAs (9.8 colonies/100m^2 for Arrecifes Tourmaline NR and 7.1 colonies/100m^2 for Tres Palmas MR) where the overall mean was significantly higher (Kruskal-Wallis test p=0.00) (Fig 2). On average the largest colonies were observed at Tres Palmas MR and Arrecifes de Tourmaline NR while the greatest proportion of smaller sized colonies (50-99 cm length) was seen at Canal Luis Peña NR.

A total of 1,387 colonies were quantified and measured throughout all MPAs. The number of colonies assessed per study site varied from 5 at Punta Guaniquilla to 586 at Arrecifes de Tourmaline. Due to the low number of colonies available in Punta Guaniquilla NR and Bahías Bioluminiscentes de Vieques NR the data from these areas is not included in further analyses.

Percent live tissue cover per colony averaged highest at Arrecifes de la Cordillera NR (87%) followed by Tres Palmas MR (77%) and was lowest at Canal Luis Peña NR (61%). Mean LAI varied between 1.4 and 14.9 m^2 per survey area. Colonies at west coast sites showed significantly higher LAI (Kruskal-Wallis test p=0.00) over east coast sites (Fig 3).

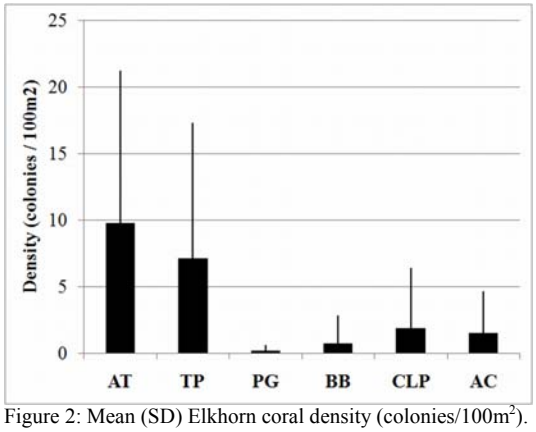

Figure 2: Mean (SD) Elkhorn coral density (colonies/100m^2).

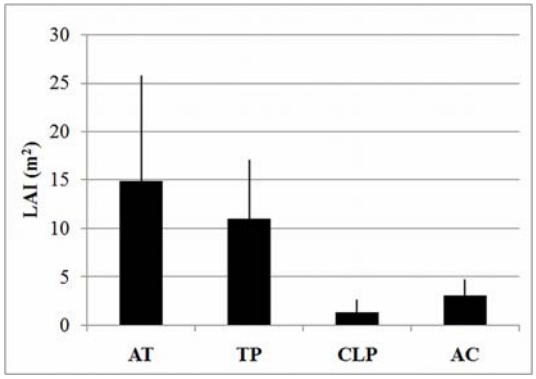

Figure 3: Mean (SE) live area index (LAI) per survey area (m^2) for survey areas where *A.palmata* was present.

Infestations of corallivorous snails (*Coralliophila abbreviata*) were observed on 3% of all colonies although this ranged from 0.9% in Arrecifes de Tourmaline NR to 10.6% at Canal Luis Peña NR. Snail occurrence rates were higher on the east coast which had lower Elkhorn densities and smaller colonies. Average number of snails per colony ranged from 2.6 for Arrecifes de Tourmaline NR to 5.1 at Arrecifes de la Cordillera NR. The frequency and number of snails was highest at Canal Luis Peña NR and Arrecifes de la Cordillera NR and the occurrence was inversely related to the density of colonies over all sites sampled.

Disease was observed on 6.7% of colonies averaged over all sites (range from 4% at Tres Palmas MR to 9% at Arrecifes de Tourmaline NR) and most of the diseased colonies were classified as such due to patchy necrosis (white pox disease). White band disease (WBD) affected 2.4% of all colonies and was most prevalent in Arrecifes de la

Cordillera NR (4.7%) and Canal Luis Peña NR (1.6%) while only 1% occurred at Arecifes Tourmaline NR and none were observed at Tres Palmas MR. Partial bleaching (<20% of colony) was observed in Tres Palmas MR (3 colonies) and Arrecifes de Tourmaline NR (2 colonies) on the west coast. Recent mortality estimates ranged from 0.1% of the colony to 40%. The greatest percentages of the colony affected by recent mortality were attributed to competition with the encrusting sponge *Cliona tenuis* (only at west coast sites) and diseases.

Those MPAs with lower densities of live *A. palmata* (Punta Guaniquilla NR, Canal Luis Peña NR and Bahías Bioluminiscentes de Vieques NR) were not considered suitable for permanent long-term monitoring. This was mainly due to the limitations of the protocol for demographic monitoring (Williams *et. al*. 2006) in which areas with low density of *A. palmata* or depths less than 2 m are unsuitable. Three permanent monitoring plots were established at each of three MPAs (Arrecifes Tourmaline NR, Arrecifes de la Cordillera NR and Tres Palmas MR) in October of 2007 for demographic purposes. The frequency distribution of size classes in the permanent plots showed a greater proportion of small colonies in Arrecifes de la Cordillera (Fig. 4).

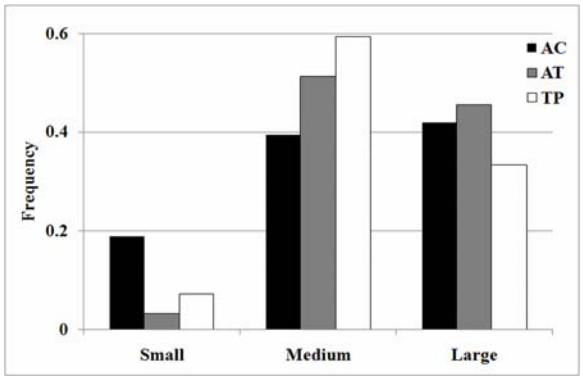

Figure 4: Frequency distribution of all colonies by size classes at long-term monitoring plots in AC (N= 117), AT (N=156) and TP (N=138). Size classes based on amount of live tissue: Small < 50 cm^2, Medium 50 cm^2 – 1,600 cm^2, Large > 1,600 cm^2.

After six months, three (2.7%) permanently tagged colonies were dead and 18 (16.7%) were unaccounted for within the permanent plots. No significant changes in live tissue cover were observed for the colonies that remained. The mean LAI for each plot decreased at Arrecifes de la Cordillera over the first six months of sampling (Fig. 5).

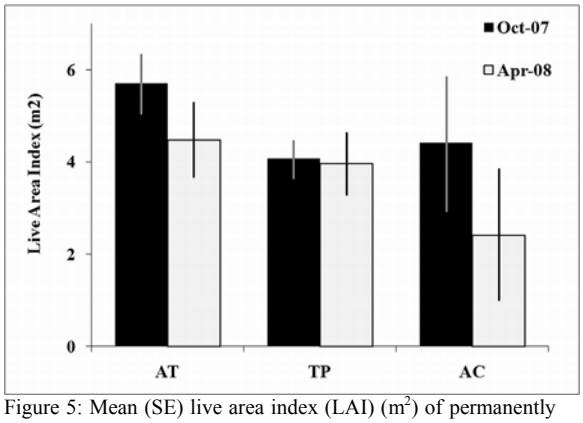

Figure 5: Mean (SE) live area index (LAI) (m^2) of permanently tagged colonies per plot over two sampling periods.

Discussion

In this study we estimate that potential Elkhorn coral habitat occurs in an area approximately 673 km^2 around the Puerto Rican archipelago. In order to improve this estimate greater resolution bathymetric and habitat maps are necessary to refine the scale of potential habitat. Ground-truthing of additional sites where it was documented in the past (Goenaga and Cintrón 1979) will help improve the estimate further accounting for spatial variability as this species is known to be patchy in distribution.

Within the 6 MPAs the proportion of area where Elkhorn coral was present (30% of high probability potential habitat) was lower than an island-wide estimate of 88% conducted during the late 1970's (Weil et al*.,* 2002), although methods differ. On the eastern coast the presence of Elkhorn was observed at 37% of sites (Weil et al*.,* 2002) which is comparable to this study's estimate of 36% pooled for three east coast sites. Nonetheless, total loss in Elkhorn coral was evidenced in 13.6% of the random survey areas where only dead standing skeletons were present (range 0% - 42%) which can be extrapolated to an estimate of 15 km^2 island-wide and is supported by the observation of large thickets of dead standing Elkhorn.

The proportion of random survey areas where live Elkhorn was present varied greatly among MPAs (14% - 73%) and the higher estimate from Arrecifes Tourmaline is comparable to results obtained by Mayor et al. (2006) (74%) in St. Croix, USVI. However, the maximum depth sampled in Puerto Rico was 5 m and in St. Croix it was 10 m. The overall density from this study (3.3 colonies/100 m^2) was higher than St. Croix (1.6) and Venezuela (3.1) (Mayor et al*.,* 2006; Zubillaga et al*.,* 2007), however comparison of density estimates among studies is troublesome due to difference in methods and the limits of areas surveyed.

On average the Elkhorn populations within the MPAs on the east coast of Puerto Rico seem to be in relatively poorer condition due to lower density, size, live coral cover and higher rates of disease, recent mortality and predation by snails. Canal Luis Peña, Culebra had the lowest mean live coral cover per colony and the smallest sized colonies with resulting low mean LAI. Arrecifes de la Cordillera had the highest mean live tissue cover per colony of all sites but it lacked large sized colonies which reduced the mean LAI for the site. Since small colonies make up a greater proportion of the population at east coast sites this may reduce their ability to withstand bleaching, disease and predation impacts as less live tissue is available to be lost.

White band disease (WBD) was observed in 2.4% of all colonies yet the greatest proportions were observed in east coast sites of Puerto Rico. In St. Croix the overall prevalence of WBD was 3.2% (Mayor *et. al.,* 2006) while in Los Roques, Venezuela it varied between 0.4 and 4.7% (Zubillaga *et. al.,* 2007) suggesting that Elkhorn coral threats demonstrate high variability within geographical regions, although temporal factors may also affect the patterns observed.

The overall proportion of colonies with snails averaged 3.7% (range 0.9 to 10.6%) which is lower than previous reports for Puerto Rico (e.g., 18%, Bruckner *et. al.,* 1997), yet this is highly variable. At east coast sites colonies had groups of 10 to 18 snails while the west coast sites had occurrences of less than 6 snails per colony. Mean number of snails per colony was 5.1 at Arrecifes de la Cordillera, higher than the 3.7 estimated for La Parguera (Bruckner 2000).

Long-term monitoring for Elkhorn coral in Puerto Rico initiated in 2007 showed a decrease in LAI for colonies tagged in Arrecifes de la Cordillera. Although no significant changes in mean percentage of live tissue cover were detected, the loss of 12 colonies at this site reduced total plot LAI. The loss of whole colonies was caused by the unusually large swell event that occurred during March of 2008 with long period waves reaching up to 12 m in height (National Weather Service, NOAA). Other sites also had detached and broken colonies, yet impact was most notable in northern sites of Arrecifes de la Cordillera and at Tres Palmas MR the number of loose fragments was lower than at other sites.

The potential habitat for *A. palmata* calculated for the Puerto Rican archipelago is a first step towards better understanding the population's spatial and temporal trends. As a population declines, a combination of reduced extent and density is expected, yet extrapolating results from a few sites can be misleading. Our results suggest differences in the occurrence, distribution and condition over the scale of Puerto Rico. The method used to evaluate the distribution of Elkhorn within MPAs provides a spatially explicit baseline upon which changes can be evaluated, which in combination with the demographic monitoring will enhance our understanding of population dynamics of Elkhorn coral in the Puerto Rican archipelago.

1) University of Hawaiʻi at Hilo, 200 W. Kawili St. Hilo Hawaiʻi 96720 USA

Abstract. The health states of scleractinian corals were assessed at Waiʻōpae, southeast Hawaiʻi Island, where approximately half of the tide pools belong to a Marine Life Conservation District (MLCD) while the other half lies outside the MLCD boundary. The susceptibility of corals to afflictions is species-dependant with *Porites compressa* being the most (22.5±3.9% unhealthy) and *Pavona varians* the least (1.1±0.27% unhealthy) susceptible. The proportion of unhealthy corals was: higher inside the MLCD than outside for *Montipora* and *Pocillopora*; not different between the two areas for *Porites*; and higher outside MLCD than inside for *Pavona*. Skeletal growth anomaly (SGA) was disproportionably observed in *Montipora* spp., especially *M. capitata*, 13.6 (±0.37) % of which were afflicted by this condition. There is no clear correlation between the progression of SGA (change in size or frequency) and species, location, or season. Some coral colonies are showing a level of resilience against SGA while others have succumbed to it within the Waiʻōpae population. The prevalence of coral afflictions at Waiʻōpae is unusually high compared to other sites in the Hawaiian Archipelago, but the causes are unknown. Monitoring of coral health at this site is continuing with an incorporation of assessment of correlations to water quality characteristics.

Key words: coral disease, skeletal growth anomaly, Waiʻōpae, Hawaiʻi, *Montipora*

Introduction

Prevalence and severity of coral diseases are reported to be increasing worldwide (reviewed in Harvell et al. 2007). Types of diseases or reduced health states seem to vary according to coral species and location. In many cases, the effort to positively identify the pathogen responsible for the onset of coral diseases has been met with challenges. It is generally believed that water quality exacerbates the susceptibility of corals to pathogenically or non-pathogenically compromised health. For example, moderate increases in nutrient concentrations have been shown to substantially increase the severity of coral diseases (Bruno et al. 2003). However, specific causal relationships between particular water quality characteristics and individual coral disease are poorly understood. With the mechanisms of disease progress and mortality of corals being poorly understood, it is quite plausible that disease could even enable coral survival through reproduction of disease resistant genotypes in some cases (Lesser et al. 2007). Until the effects of coral diseases are better understood it is difficult to assess the fate and threat posed to corals in waters subjected to harmful anthropogenic influences.

Coral reefs surrounding high gradient island systems, such as Hawaiʻi, are particularly vulnerable to influences from terrigenous sources. This is especially true on the island of Hawaiʻi because the substrate is predominately composed of porous basaltic rock and, being young on a geological timescale, lacks an abundance of soil for bioremediation. Further compounding these effects is the human population growth. Hawaiʻi Island has experienced one of the fastest human population growths over the last decade or so (23.6% increase in 1990-2000) in the State of Hawaiʻi (U.S. Census Bureau 2000). Synergistically, these factors have a great potential to produce direct anthropogenic effects on fringing coral reef ecosystems.

Some of these effects can be manifested in states of reduced health of corals. Several symptoms for poor health in reef-building corals have been reported in Hawaiʻi and range from bleaching, coral tissue loss, infectious diseases for which pathogens have been identified, and other abnormalities in cellular, tissue, and skeletal morphologies of unknown causes (Gulko et al. 2000, Friedlander et al. 2005, Sutherland et al. 2004). Coral diseases have been found on most major coral species of the main Hawaiian islands (*Porities lobata, P. compressa, Montipora capitata, M. patula, and Pocillopora meandrina*: Gulko et al. 2000, Friedlander et al. 2005). The last few decades has seen an increase in the frequency of coral diseases over a range of depths and habitats in Hawaiʻi (Gulko et al. 2000, Friedlander et. al 2005). Different coral genera exhibit different types and prevalence of diseases at different locations in Hawaiʻi (Aeby 2004, this study). These conditions, with the exception of

bleaching, are poorly studied. In fact, it is not clear how well these coral conditions adhere to the definition of disease because the mechanisms and degree of functional interruption are largely unknown.

Hawai‘i Island is the largest of all Main Hawaiian Islands and contains some of the most well-developed coral reefs. However, data on diversity, abundance, and distribution of compromised health conditions in corals around Hawai‘i Island are largely absent thus far. Our monitoring program has been surveying corals in the tide pools at Wai‘ōpae, Hawai‘i Island, the southern part of which was designated as a Marine Life Conservation District (MLCD) where no collection of any organisms is allowed. The initial results of prevalence rates and changes in types of unhealthy states in corals from 2006 to 2008 are presented here.

Material and Methods

All field surveys were conducted in Wai‘ōpae tide pools that fall inside and outside of the MLCD (19°29’55”N 154°49’06”W, Fig. 1).

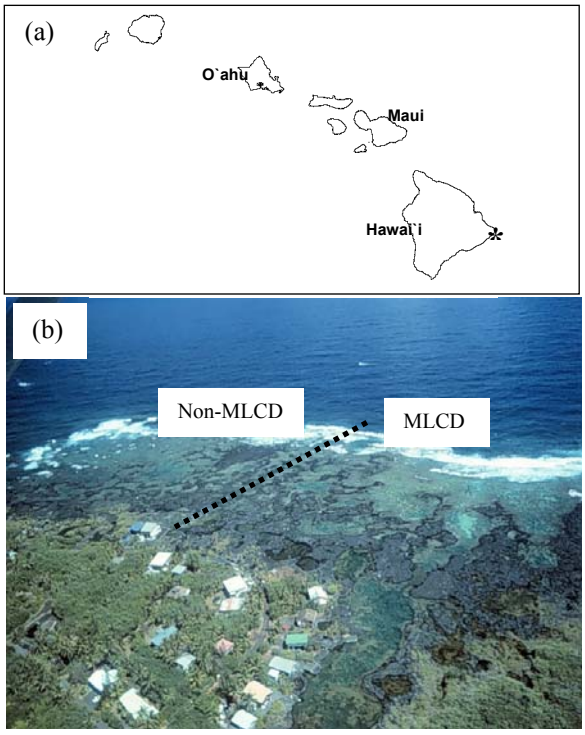

Figure 1: (a) Map of Main Hawaiian Islands showing the location of Wai‘ōpae on Hawai‘i Is., indicated by *. (b) Aerial photograph of Wai‘ōpae tide pools showing the boundary (broken line) of the Marine Life Conservation District. Note that this photograph was taken circa 1999. Currently there are many more houses along the shoreline. Photo taken by J. Coney, UHH.

For transect surveys, coral colonies along six randomly placed 25m transect lines each inside and outside of the MLCD were surveyed on four occasions in 2006 and again in June 2008. Coral colonies along these transects were identified to species, and proportions of colony areas occupied by various health states were visually estimated. To monitor changes in the health state of individual coral colonies, locations of four colonies of each of the six most common coral species(*Montipora capitata, M. flabellata, M. patula, Porites lobata, Pocillpora meandrina, Pavona varians*) were recorded inside of the MLCD, and four additional colonies of each species outside of the MLCD. These coral colonies were originally randomly selected regardless of their health status and repeatedly observed monthly between Feb 2007-March 2008 by both visual inspection and image analysis. For the image analysis, a photo was taken from the plain parallel to the coral colony within the frame size that fit the entire colony. The relative areas of the entire colony and that of unhealthy states were calculated using an image analysis software, ERDAS Imagine 9.1 (Leica Geosystems) at the GIS Laboratory at University of Hawai‘i at Hilo. All statistical analyses were performed using Minitab 15 (Minitab Inc.).

Results

The pooled survey data from randomly placed transects in 2006 and 2008 showed that the ten most common scleractinian coral species found at Wai‘ōpae had significantly different (Kruskal-Wallis test, $p<0.001$) prevalence of colonies showing symptoms of any unhealthy states, with *Porites compressa* and *Montipora capitata* being most unhealthy and *Pavona varians* being the most healthy (Fig. 2).

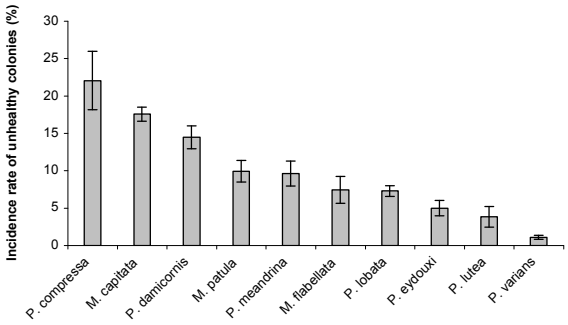

Figure 2: Mean incidence rates (% ± std. error, n=6-694) of unhealthy corals according to species at Wai`ōpae, Hawai‘i pooled from the 2006 – 2008 random transects.

The susceptibilities to different types of afflictions were species- and genus-dependent. Comparison among common genera showed significant differences among genera in susceptibility to bleaching, skeletal growth anomalies, and tissue loss of unknown causes (Kruskal-Wallis, $p<0.001$) with

Montipora being the most susceptible to all three conditions (Fig. 3).

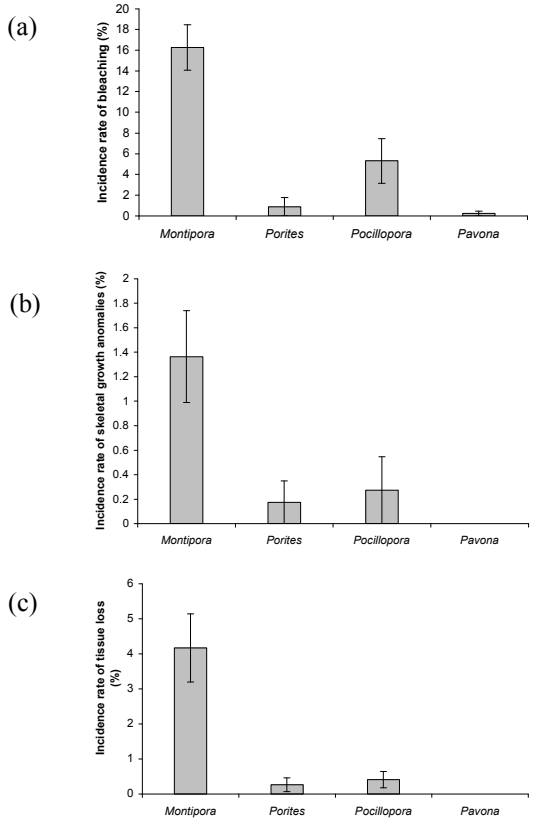

Figure 3: Mean incidence rates (% ±std. error, n=22-121) of (a) bleaching; (b) skeletal growth anomalies; and (c) tissue loss observed in the four most common coral genera at Wai`ōpae, Hawai'i from the 2006 – 2008 random transects.

Comparisons of incidence rates of unhealthy colonies between inside and outside of the Wai'ōpae MLCD revealed no consistent trend across coral genera (Fig. 4). However, the individual genus data showed that the prevalence of unhealthy colonies was higher inside the MLCD than outside for *Montipora* and *Pocillopora* (both $p<0.00$), same between two areas for Porites ($p>0.05$), and lower inside the MLCD than outside for *Pavona* ($p<0.05$) (Fig. 4).

The monthly repeated observations of coral colonies representing the six most common species have produced a large database of image archives that will continue to expand. With these images, skeletal growth anomalies were the easiest to track since the growth anomalies have well defined boarders that can be traced by image analysis. *Montipora capitata* showed the highest incidence rate of skeletal growth anomalies of all coral species in the random transect surveys of 2006-2008 (19.32±3.91%, data not shown).

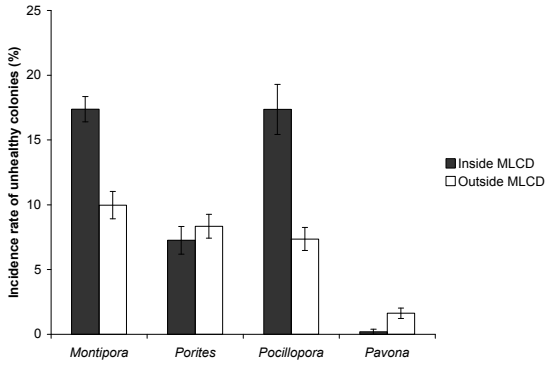

Figure 4: Comparison of the mean incidence rates (% ± std. error, n=77-612) of unhealthy corals inside and outside of the Wai'ōpae Marine Life Conservation District (MLCD) separated into the four main genera.

The size of skeletal growth anomalies was expressed as relative to the entire coral colonies that housed them to account for growth of corals. Generally, the relative size of skeletal growth anomalies increased slightly or remained the same both inside and outside of the MLCD between February 2007 and February 2008 (Fig. 5). In one of the 8 colonies, the skeletal growth anomaly occupied >90% of the entire colony surface for the duration of our observations, eventually resulting in death of the entire colony by February 2008 (Colony "In 1", Fig. 6a-b). Other *M. capitata* colonies maintained the same relative sizes of skeletal growth anomalies (e.g. Colony "In4", Fig. 6c-d) or remained completely devoid of growth anomalies for the same observation period. Overall, there were no significant correlations between the skeletal growth anomalies (change in size or frequency) and species, location, or season (all $p>0.05$).

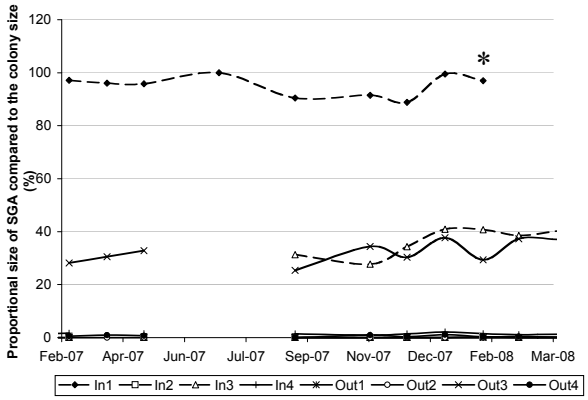

Figure 5: Changes in the sizes of skeletal growth anomaly (SGA) proportional (%) to the whole colony size of four repeatedly analyzed *M. capitata* colonies inside the MLCD ("In1"-"In4") and four colonies outside ("Out1"-"Out4"). Data for July 2007 for colonies except Colony "In1" are unavailable. *The first colony inside the MLCD ("In1") completely died; see Fig. 6.

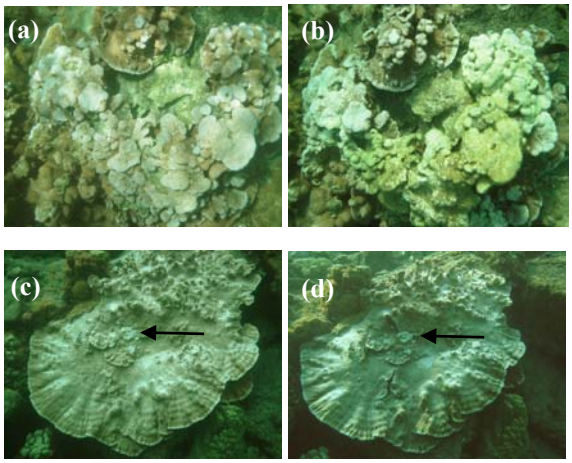

Figure 6: Examples of changes in skeletal growth anomalies in repeatedly observed *Montipora capitata* colonies at Wai`ōpae, Hawai'i. Colony "In1" in February 2007 (a) and in February 2008 (b), showing the expansion of skeletal growth anomalies (shown as white patches with anomalous textures in the photos) resulting in the colony's death by February 2008. Colony "In4" in February 2007 (c) and in February 2008 (d), showing no change in the relative size of the skeletal growth anomaly (indicated by arrows) over the same period of time.

Discussion

Hawaiian Archipelago showcases geologic history in a linear geographic scale from the southeast end to the northwest extreme. Hawai'i is the southern-most, and thus youngest (<500,000 years old, Juvik and Juvik, 1998), island of the archipelago. The incipient fringing reefs around Hawai'i Island, therefore, signifies the beginning of coral reef ecological succession along the Hawaiian island chain. Despite such a young geologic age, the reefs at Wai'ōpae on the east side of Hawai'i Island boast a relatively high level of live coral cover (mean 38.9% cover outside of the MLCD and 44% inside, 2004 surveys Hallacher et al. unpublished). Our monitoring program that began in June 2006 which is still continuing has depicted the health status of coral species there.

The incidence of unhealthy corals at Wai'ōpae is much higher than other Hawaiian locations. What is especially anomalous, visibly and statistically, is the number of *Montipora* that have succumbed to afflictions, especially to skeletal growth anomalies. For example, Aeby (2004) found the mean incidence rate of unhealthy *Montipora* to be less than <1% in uninhabited Northwestern Hawaiian islands, compared to 22.1% at Wai`ōpae. Our preliminary surveys have found that the proportions of *Montipora* colonies with skeletal growth anomaly were <1% at Leleiwi and Ke`ei (data not shown), both sites near relatively high human populations on Hawai'i Island.

There is an on-going debate on whether pathogens are the primary cause of coral diseases or if pathogens incite secondary opportunistic infection or reaction when corals are already under physiological stress (Harvell et al. 2007, Lesser et al. 2007). The physiological function of coral colonies may change due to environmental stress affecting the coral, resulting in altered environmental conditions for coral-associated bacteria (Pantos et al. 2003). Regardless of directness of the link, reports are suggesting that increases in the number of both new diseases and species affected are linked to human-induced alterations in coral reef environments both in terms of land-based sources of pollution, sedimentation, and eutrophication as well as global climate changes such as seawater temperature rises and ocean acidification (Bruckner & Bruckner 1997, Harvell et al. 1999, Porter et al. 2001, Rosenberg & Ben-Haim 2002, Sutherland et al. 2004, Bruno et al. 2003, Pantos et al. 2003, Aeby 2004). Most studies have been unable to identify exogenous organisms or intracellular infection by parasitic agents for skeletal growth anomalies. It has been suggested that anomalous skeleton formation and growth may be influenced by environmental factors; however, no clear correlation has been established. Several investigators have postulated that disease incidence might be associated with elevated nutrients with or without sediment loads delivering potentially pathogenic organisms to the marine environment (Richardson 1998, Sutherland et al. 2004, Breitbart et al. 2005, Bruno et al. 2003).

Causes of the observed high rates of unhealthy states in corals at Wai'ōpae are also not known. The porous basaltic substrate and proximity of the reef to the coastline due to the absence of continental shelf or well-developed reef crest found at this site are typical of other windward locations on the same island. What might be negatively affecting environmental conditions for benthic organisms at Wai'ōpae is the reduced water circulation due to the substrate forming tide pools. All of the corals that were surveyed in this study were found in tide pools with varying levels of connection to open water. The water circulation pattern in Wai'ōpae tide pools has not been investigated but is expected to be very complex because of the high level of complexity in substrate topography as well as freshwater inputs through groundwater and land runoffs. At low tides, many of the tide pools are ponded, whereas the seawater level at high spring tides covers the tops of tide pool walls and reaches the residential houses along the shoreline.

Water quality inside the tide pools would likely affect benthic organisms such as corals more than mobile organisms. If coral afflictions at Wai'ōpae are direct or indirect results of terrigenous stressors, than accumulation of runoff, groundwater, and reduced water circulation at low tides must be exacerbating their effects. This might partially explain why the

coral genera that are more susceptible than others, such as *Montipora* and *Pocillopora*, are showing higher unhealthy rates inside the MLCD than outside the MLCD (Fig. 4). The tide pools inside the MLCD are more isolated and ponded at low tide than those outside the MLCD (Fig. 1b). Another compounding effect that has the potential of creating differences in stressor level in tide pools inside and outside the MLCD is the human use. Of the estimated 87,190 people who visited Waiʻōpae during 2004-2005, 90.0% of them stayed within the 50-acre MLCD (Shea Flanders and Settlemier, 2007). A larger proportion (36%) of people participated in non-consumptive underwater activities, such as snorkeling, inside the MLCD than outside (21%, Shea Flanders and Settlemier, 2007). The MLCD at Waiʻōpae was designated as a no take zone in 2003. The effect of this MLCD designation needs to be carefully assessed in terms of the benefits of various species protection at the cost of increased visitor attraction and usage. These results from coral monitoring illustrate the complexity of the many factors influencing coral health. More detailed analysis comparing multiple environmental differences inside and outside the MLCD may shed light on what elements must be incorporated into conservation protection in order to adequately address coral health concerns.

It is not known when the health states of corals at Waiʻōpae began to deteriorate to the present levels because there had been no regular monitoring effort focusing on the health of corals there before this program. Regarding skeletal growth anomalies specifically, the disease state does not seem to advance rapidly (Fig. 5 and Fig. 6). One exception to this was found in the colony, "In1", that was heavily (>90%) covered with skeletal growth anomaly for 10 months of our observation without showing further deterioration before succumbing rapidly to turf algal invasion in the last two months (Fig. 5). In order to monitor changes in health conditions of corals at Waiʻōpae effectively, we will continue our periodic random transect surveys and photo documentation of repeatedly observed colonies. Current efforts are being focused on evaluating the water quality in Waiʻōpae tide pools and assessing potential correlations between water quality characteristics to incidence, types, and progression of coral afflictions.

Abstract. On December 26, 2004, the impact of tsunami waves caused by an undersea earthquake off Sumatra Island generated severe damage to coastal communities throughout the Indian Ocean. One year before the Indian Ocean Tsunami (IOT), we established permanent survey plots in characteristic mangrove forests on the coast of Ranong, Thailand. Since then, we have continued to survey mangrove stands and macrobenthic communities. Damage caused by the IOT included immediate damage and gradual indirect mortality, but the damage to mangrove ecosystem was limited and habitat specific with 6% to 16 % of mangrove stands showing damage one year after the tsunami. Although population density and biomass of macrobenthic organisms were not affected by the tsunami, diversity decreased in some areas. The community structure of macrobenthic organisms in mangrove swamps was affected: endobenthic organisms decreased due to an increase in the abundance of coastal sand in the sediments; epibenthic organisms initially decreased but recovered gradually; and terrestrial epibenthic organisms increased on dried sandy substratum.

Key words: natural disaster, Thailand, tsunami, macrobenthos, Andaman Sea, mangrove forests

Introduction

Mangroves play important roles in coastal ecosystems of the tropics and sub-tropics producing of a lot of litter which provides food and energy to the aquatic flora and fauna. Mangroves also provide fundamental ecological services to local inhabitants (Aksornkoae 1993; Hogarth 1999; Barbier and Sathirathai 2004). Many studies have been done on mangrove distribution and productivity, both in forest stands and aquatic systems, however, there is insufficient knowledge on the disturbance of mangrove ecosystems by large natural disasters such as the tsunami which is different from usual ocean waves and on the process of recovery from such catastrophic damage.

On December 26th, 2004, the impact of tsunami waves caused by an undersea earthquake off Sumatra Island generated severe damage to artificial constructions and some natural ecosystems on coastal area along the Andaman Sea (MNRE 2005; UNEP 2005; Stoddart 2007). Mangrove stands suffered unprecedented damage by both direct impact from the waves and floating material and also more gradual indirect symptoms caused by root damage due to piles of thick sand brought by the tsunami (Matsumoto et al. 2006). The tsunami also disturbed fish and benthic communities which play a very important role in mangrove ecosystems.

One year before the tsunami disaster, we established permanent survey plots in some characteristic mangrove forests on the coast of Ranong area facing the Andaman Sea, Thailand. Since then, we monitored regularly the dynamics of mangrove forests and macrobenthic communities which utilize them as habitat and potential food sources. These areas suffered severe damage from the tsunami on human lives, infrastructure and mangrove ecosystems, and therefore, we could obtain comparable data to show disturbance patterns and to evaluate the recovery process in mangrove ecosystems. In this study, we demonstrate the initial process of recovery from damage over a few years on mangrove forests and macrobenthic communities.

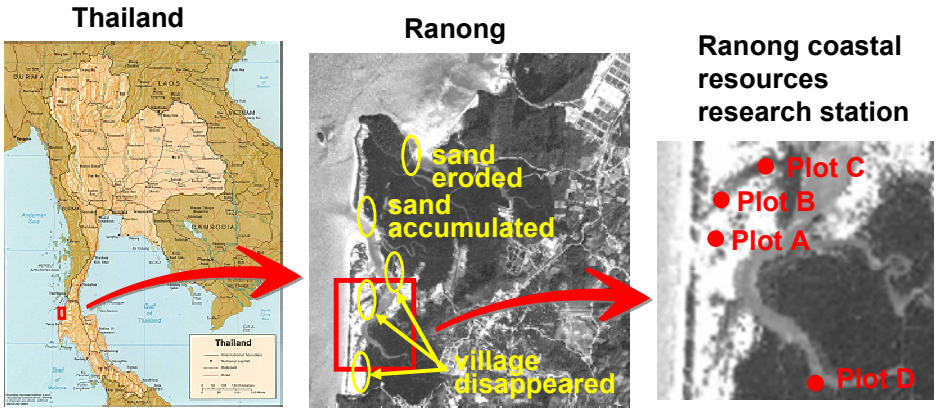

Figure 1: Map of Ranong, southern Thailand, showing the study sites in Ranong coastal resources research station, Kasetsart University

Material and Methods

Four study plots (Plots A-D) of mangrove forests were established in the vicinity of Ranong coastal resources research station (RCRRS) (9°23'N 98°24'E), Kasetsart University, situated on the Andaman coast of Suksamran sub-district, Ranong province, southern Thailand (Fig. 1). Plot A was *Avicennia alba* Blume forest located at the interior tidal inlet branched from main river. Plot B was a complex forest of *A. alba* and *Rhizophora mucronata* Lamarck located at the mouth of a tidal inlet branching off the main river. Plot C was *R. mucronata* forest on the bank of the main river. Plot D was also *R. mucronata* forest in an interior mangrove estuary outside the station. These mangrove stands were harvested and regenerated about 15-20 years previous to the begin of our study in 2003.

All mangrove trees within 500-1,000 m^2 areas were continuously monitored in every plot before and after the tsunami. Diameters above the neck of the highest root were measured. Damage to mangrove stands was estimated from loss of trees by comparing data before and the after the tsunami.

Soil and sediment at each study site was collected from the surface to a depth of 20 cm using an acrylic core with a 44 mm diameter, and grain size composition was analyzed by a series of phi-scaled mesh sieves. Taxonomic composition, density and biomass of epibenthic organisms were investigated quantitatively using a 50 cm x 50 cm quadrat set at random on the ground. Five replicate samples of sediments were collected from the surface to the depth of 10 cm at every site. The collected soils were sieved using a 500 µm mesh sieve and preserved with 10% neutralized formalin. Macrobenthic specimens were identified to the lowest taxonomic category possible. The total weight of each species was measured using an electric balance after being picked out from the residue under a dissecting stereo microscope. The survey was conducted before the tsunami on September 26, 2003 and after the tsunami on March 15, 2005 and November 23, 2006.

Population density and biomass were calculated as the number of individuals (n/m^2) and the wet weight (g/m^2) per square meter, respectively, for every species/taxa. Species richness and diversity index

Figure 2: Serious tsunami damages in the survey areas just after the tsunami (March 2005).

1. *Rhizophora* forest was destroyed by 10 m width along river (near Plot C).
2. *Rhizophora* - *Xylocarpus* stands were mown down and buried by sea sand more than 1 m thick (river mouth).
3. Concrete boardwalk for mangrove observation on *Avicennia* forest was broken by direct wave impact (Plot A)
4. Sands were carried by waves from the beach onto the floor of *Rhizophora* forest (Plot B).

were calculated for every plot. Species diversity was calculated using the Shannon-Weaver Index H'=-Σ(n/N)log(n/N), using logarithmic base 2, where 'n' is the number of individuals for each species/taxa, and 'N' is the total number of individuals.

Results and Discussion

The tsunami damaged many human lives and much property in coastal areas as well as natural ecosystems (MNRE 2005; UNEP 2005; Stoddart 2007). Examples of tsunami damages in the survey areas are presented in Fig. 2. The damage by the tsunami was caused by immediate direct impacts of floating materials as well as extremely strong wave action and backwash. Some mangrove forests suffered decline/death after being buried by sand.

In Plots A, B and C, 6.5-16.1% of mangrove stands were damaged (Fig. 3). Smaller trees suffered more damage than the larger ones, especially in Plot A (Fig. 3).

It was assumed that the damage to mangrove stands in the survey areas was due to direct and indirect causes. Gradual indirect lethal symptoms seemed to be caused by: 1) root damage due to strong shaking or disturbance of root respiration by accumulated sand carried by the tsunami; and 2) damage by sea water abnormally accumulated in the forests and the surrounding soil (Matsumoto et al. 2006).

Composition of sediment grain size of four survey plots and the neighboring beach were compared (Fig. 4). Mean particle size of sediment was the largest and well sorted in Plot C, followed in Plots A and B, and the smallest in Plot D. A considerable amount of accumulated sand (mainly 125 - 250 µm) of which the tsunami brought from the sub-tidal parts of the neighboring coast were included in the sediments of Plots A, B and C.

When we surveyed three months after the tsunami in March 2005, we found that approximately 5-10 cm of sand had accumulated on the substratum in Plots A, B and C. (observations in March 2005; Fig. 2.4). Sediment conditions recovered gradually in the two years after the tsunami. Situated in a tidal inlet the bottom substrate was exchanged frequently by routine tidal flow and by bioturbation by benthic organisms such as crabs, *Uca* spp., horn snails, *Cerithidea cingulata*, and some polychaetes.

Mollusca (36 taxa) constituteed the most dominant and diverse taxa, followed by Arthropoda (21 taxa) and Annelida (9 taxa). Dominant in the survey areas were: *Nerita violacea*, *Cerithium coralium*, *Cerithidea cingulata*, *C. quadrata*, *C. obtusa*, *Telescopium telescopium*, *Littoraria pallescens*, *L. strigata*, *Assiminea brevicula*, *Stenothyra ovalis*, *Cassidula nucleus*, *Ellobium aurisjudae* (gastropods), *Saccostrea forskali*, *Gelonia erosa* (bivalves), *Perinereis* spp. and Capitellidae (polychaetes), *Parasesarma pictum*, *Episesarma* spp., *Uca annulipes*, *U. vocans*, *Thalassina anomala* (crustaceans) and some insects.

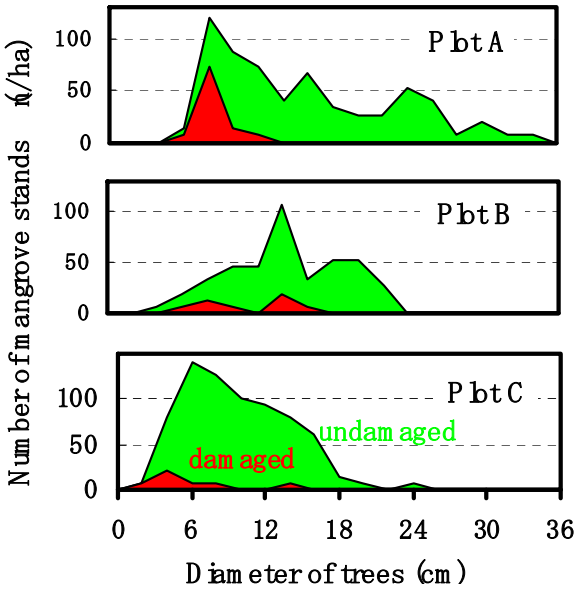

Figure 3: Damage to mangrove stands seen one year after the tsunami (until November 2005). Red: Damaged tree, Green: Undamaged tree.

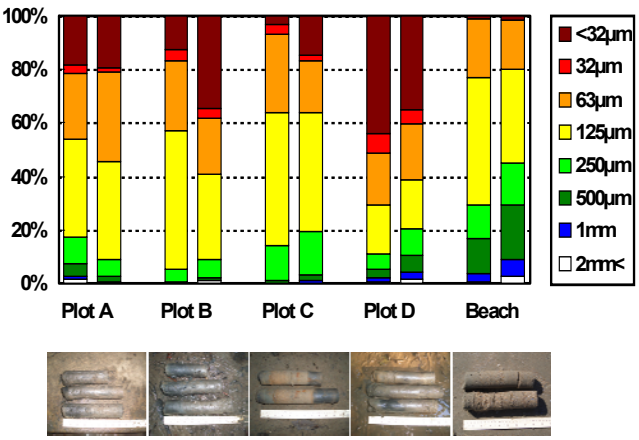

Figure 4: Composition of sediment grain size two years after the tsunami (November 2006) on four survey plots and the neighboring beach. Left bar: 0-10 cm deep, right bar: 10-20 cm deep. Photos below every plot represent the core samples in which left side of every photo is the surface layer of the substratum.

When we surveyed three months after the tsunami in March 2005, we found that almost all macrobenthic organisms, except for a few epibenthic gastropods inhabiting stem and root of mangrove trees, were buried in sand transported from nearby shallow ocean waters or the neighboring beach (Fig. 2.4). Population density (number of individuals), biomass (wet weight), and diversity (number of species/taxa and diversity indices) of macrobenthic organisms were compared before and two years after the tsunami (Fig. 5). The population density and the biomass measures were very high in Plot A in which the maximum density and biomass of horn snails, *Cerithidea cingulata*, exceeded 1,000 individuals/m^2 and 200 g/m^2, respectively, including many juveniles. In Plot D, the population density was the highest but the biomass was not large because a large number of small

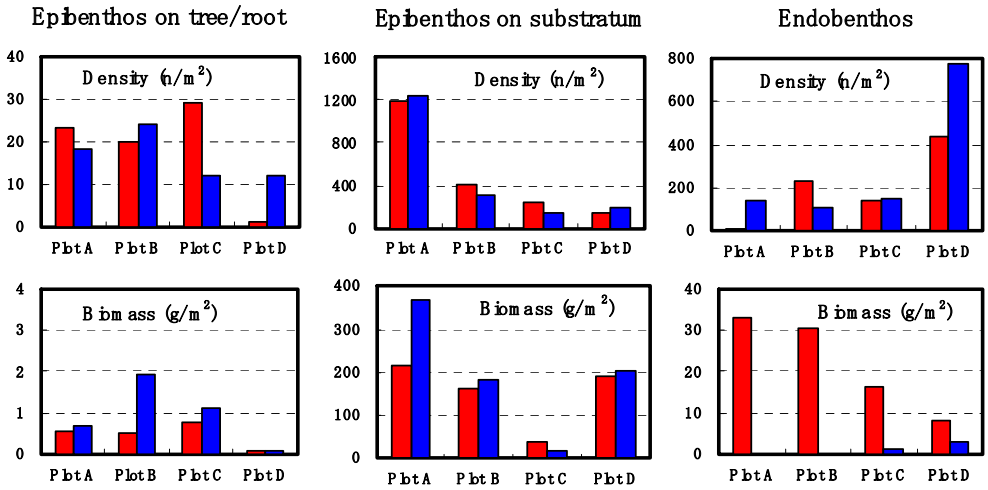

Figure 6: Population density and biomass of benthic organisms based on differences in habitat preference. Red bar: before the tsunami, blue bar: after the tsunami.

polychaetes and nematodes were included. Number of species/taxa decreased significantly after the tsunami in Plots B and C (t-test: $t = 3.89$ $p < 0.05$, $t = 14.6$ $p < 0.01$, respectively). In Plot B, the total number of species/taxa decreased 77% and the diversity index based on the number decreased 86% after the tsunami.

Population density and biomass of the following macrobenthic organisms were compared before and two years after the tsunami (Fig. 6): epibenthic organisms inhabiting stem and root of mangrove trees; epibenthic organisms inhabiting the forest floor; and endobenthic organisms living in the substratum. Although there was no distinct difference in the

density and the biomass of epibenthic organisms before and after the tsunami, the taxonomic composition changed substantially. Epibenthic organisms such as gastropods and crustaceans decreased initially (observations in March 2005) but recovered gradually. Terrestrial epibenthic organisms increased on dried sandy substratum due to immigration from neighboring forests and beaches by insects such as ants and chironomids. Biomass of endobenthic organisms decreased drastically because bivalves such as *Gelonia erosa* and polychaetes died due to the increased sedimentation by coastal sand on the floor of the mangrove forests.

The tsunami damaged many human lives and much property in coastal areas as well as natural ecosystems (MNRE 2005; UNEP 2005; Stoddart 2007), mainly in fishing villages and beach resorts facing the Andaman Sea (Matsumoto et al. 2006). These areas were characterized by shallow sub-tidal beaches and/or closed-off section of bays and low, flat land. Around our survey plots, the tsunami waves reached approximately 6 m in maximum height above ground (information from RCRRS staffs) leading to damage of mangrove ecosystems. Damage to mangrove forests and macrobenthic communities was limited and habitat specific. Although benthic organisms decreased temporarily just after the tsunami (Plots A and B), the community recovered quickly.In highly disturbed areas (Plot C) where thick sand accumulated on the bottom of the mangrove forest, recovery appears to be difficult due to altered sediment composition and depth.

Tsunami-related damage to the mangrove ecosystem was not only direct physical damage, but also subsequent decline/death/change due to salt stress, drying stress, etc., as has been discussed in some reports (MNRE 2005; UNEP 2005; Matsumoto *et al* 2006; Stoddart 2007). It is important to continue monitoring to evaluate the recovery process of mangrove forests and macrobenthic communities from the catastrophic damage.

Acknowledgement
We are grateful to the staff of Ranong coastal resources research station, Kasetsart University, for supporting the field survey. This project was partly supported by Grants-in Aids for Scientific Research from Japan Society for the Promotion of Science and Grant Program of the Sumitomo Foundation. We are also grateful to Dr. Clive Wilkinson for his valuable suggestions and editorial help to improve the manuscript.

Rapid recovery from bleaching events - Fiji Coral Reef Monitoring Network Assessment of hard coral cover from 1999-2007

E.R. Lovell[1] and H. Sykes[2]

1) School of Marine Studies, University of the South Pacific, Suva, Fiji
2) Marine Ecology Consulting, P.O. Box 2558 Govt. Bldgs, Suva, Fiji

Abstract. Long-term biological monitoring of coral reef sites across the Fiji Islands was carried out over a nine year period which included mass coral bleaching events. Sites were fringing reef slopes close to shore, or patch reefs facing deeper water, and surveys were carried out between 5 and 20m depth. Data was contributed by many organisations, including scientists, tourism operators, non-governmental organisations and community members. All surveys utilised point intercept transects from which the percentage of hard coral cover was applied for regional comparisons over-time. Benthic data was generally recorded as coral life-form categories. High sea surface temperatures (SST) in 2000 and 2002 led to large-scale coral bleaching events with hard coral mortality of 40 – 80%. In both cases, temperatures remained above the long-term summer average (28.3°C) for over 3 months. Though variable, substantial recovery to pre-bleaching levels was seen within 5 years in many areas. Fiji's reefs show great diversity, and are spread over a large geographical area. Though mass bleaching events were expansive, they did not affect the entire country's reef systems at one time. Some areas and habitats appear to have elements conducive to minimising the effects of bleaching. This allowed for the repopulating of affected areas more swiftly than may occur in reefs that are more isolated. A high level of resiliency of the Fiji reef system as a whole is indicated and is a cause for optimism.

Key words: coral reef monitoring, coral bleaching, resilience, Fijian coral reefs

Introduction

Coral reefs have been characterized as degrading worldwide (Indo Pacific (Wilkinson 2008); SE Asia (Burke et al. 2002); Caribbean (Gardner et al. 2003)). While many areas with high human population density are greatly affected by human-related impacts, in more remote areas climate change is a more immediate issue, and coral bleaching events are amongst the main factors contributing to wide scale degradation. Coral bleaching events are the main factor contributing to the wide scale degradation, having impacted coral reefs globally. However, some coral reef regions have experienced rapid recovery after major bleaching events, and such is the case in Fiji (Lovell & Sykes 2004, Sykes 2007).

Relative resilience to the widespread mortality of coral reefs during a coral bleaching event is variable. In Fiji, the rapid recolonization of affected reefs may be due largely to the size and physical complexity of the archipelago. The Fijian archipelago spans 18,500km^2 and comprises high and low islands with all reef types including one of the world's longest barrier reef (South and Skelton 2000, Vuki et al. 2000). It is a mid-ocean archipelago surrounded by deep water and washed by oceanic currents.

This paper represents a summary of annual reports submitted by the Fiji Coral Reef Monitoring Network (FCRMN) as part of its contribution to the Global Coral Reef Monitoring Network (GCRMN) and Reef Check. Data was collated from a number of organizations which include scientists, tourism operators, non-governmental organisations and community members. The programme is coordinated by the authors and the Institute of Marine Resources. It is currently supported by the University of the South Pacific and the Coral Reef Initiative in the South Pacific (CRISP).

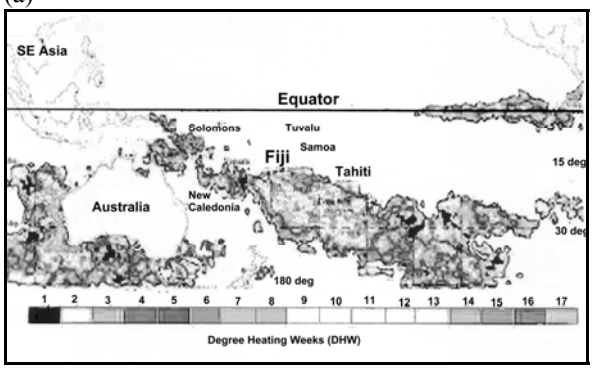
This paper summarizes the results of nine years of biological monitoring, using the Reef Check and FCRMN Point Intercept Transect (PIT) methodologies.

Background

Fiji SSTs range annually between 24°C and 28°C, with a bleaching threshold at 29.2°C (National Oceanic and Atmospheric Agency (NOAA) NESDIS satellite information).

High SSTs in 2000 and 2002 led to large scale coral bleaching events with hard coral mortality of 40-80% in depths <5m. In both cases, the temperature remained above the long-term mean and the bleaching threshold for 3 months with a band of warm water extending from the Solomon Islands to the southeast, either partially or completely covering the archipelago (Cummings et al. 2001, 2002; Lovell and Sykes 2004).

(a)



(b)

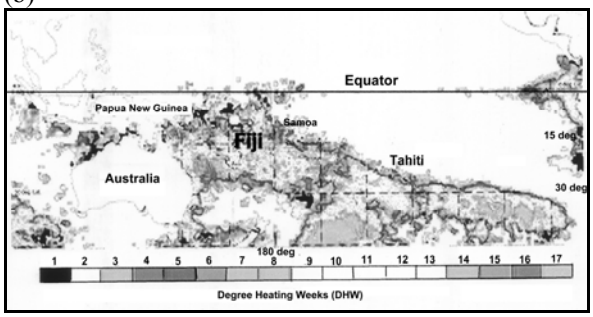


Figure 1. Chart of Degree Heat Weeks (DHW) accumulated in April, 2000 (a) and in 2002 (b) in the South Pacific. Light shading indicates 8-10 DHW's, darker shading inside of the light shading indicates 10-14 DHW's. See NOAA website: http://psbsgil.nesdis.noaa.gov:8080/PSB/EPS/SST/dhw_retro.html. National Oceanic and Atmospheric Agency (NOAA) NESDIS satellite information.

Methodology

Benthic data was assessed using point intercept transects, with the benthic attributes recorded as coral life-form categories or species. In all cases, the information was gathered over a period of years, although the most detailed and longest term data came from two areas, Suva and the central Vatu-i-Ra Passage. In-situ temperature loggers were placed in sites where biological surveys were made.

Results

In-situ temperature loggers showed a North-South sea water temperature variation of 1.5^{o}C across the archipelago (Figure 4).

For depths of 10m and deeper (<20m), benthic assessment showed a consistent trend of declining hard coral cover after the 2000 and 2002 mass coral

a)

b)

bleaching events. An increase in coral cover was evident by 2003, and by 2007 was approaching the 1999 level (Figure 5). For depths less than 10m, by 2005, the degree of coral cover exceeded the coral coverage assessed in 1999 (Figure 6). As was characteristic of all reefs, algal cover remained low except in areas where anthropogenic effects, such as nutrient pollution and overfishing, have occurred (Mosley and Aalsberberg 2003).

Figure 6. Mean hard coral and algal cover on reefs shallower than 10 m across the Fiji Islands 1999 – 2007. Error bars show standard deviation with polynomial trend lines, Order 2.

Figure 7 shows the breakdown of coral types into *Acropora* or non-*Acropora* and soft coral over the 9 years of assessment. The bleaching phenomenon in 2000, 2002, and subsequent crown of thorns seastar predation and cyclone damage had greater impacts on *Acropora* corals than on non-Acropora and soft corals. Differences in trends between Figures 5-6 and Figure 7 are due to the combination of data from all depths in Figure 6.

Figure 8. summarises the effects of coral bleaching at one site from 1999 – 2007. There was 60% live coral coverage in the Vatu-i-Ra passage in 1999. In 2000, 42% had died or were bleached. In subsequent years, partial bleaching occurred but the general level of coral coverage increased.

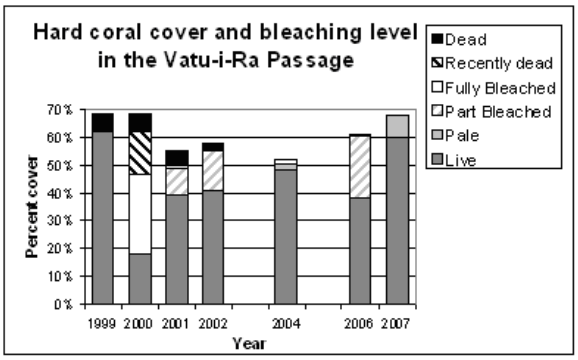

Figure 8. Hard coral cover and extent of bleaching at time of survey in the Vatu-i-Ra Passage (Mount Mutiny) 1999 – 2007. No surveys were carried out in 2003 and 2005.

In Figures 9 and 10, coral types using lifeform categories (English et al. 1997) are shown for the years 1999 – 2007, for a single site and as the Fiji-wide mean. In both cases, *Acropora* coral forms were more severely affected by bleaching than non-*Acropora*, but had recovered to pre-bleaching levels by 2005. Post bleaching reefs showed a higher diversity of coral lifeforms than pre-bleaching.

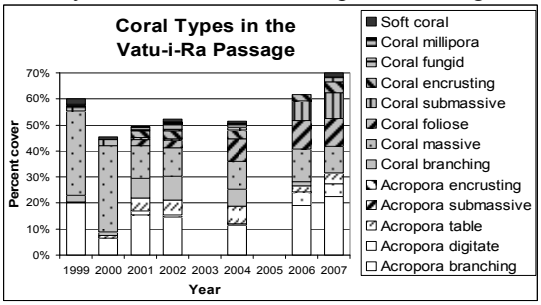

Figure 9. Mean main coral types in life-form categories at the Vatu-i-Ra Passage site 1999 – 2007. No surveys were carried out in 2003 and 2005.

Discussion

In 2000 and 2002, Fiji's coral reefs experienced extensive bleaching mortality, with a total loss of between 40 and 80% of hard coral across the archipelago. The worst affected corals were largely from the *Acropora* family, which in some areas were completely obliterated.

For a two to three year period after the 2000 bleaching, many reefs were dominated by non-*Acropora* corals, predominantly *Pocillopora*, *Porites* and *Montipora* species, but *Acropora* corals reappeared after a very short hiatus, and by 2004 equalled or exceeded pre-bleaching levels.

By 2007, coral cover was substantial on most reefs, recovering to a national average of 45%, with up to 80% live hard coral cover in some regions. In many areas recovered with hard coral cover and lifeform diversity in 2007 was higher than pre-2000 bleaching levels.

In many cases reefs which recovered quickly were down-current of unaffected areas, and so were probably connected to sources of new coral spawn. Recovery in some areas appeared to be accelerated by a cyclonic event which cleared many reefs of dead algae-coved rubble, creating new coral settlement habitat. Where recovery was slow, probable causes include physical remoteness or algae domination preventing coral settlement.

While the coral bleaching events were extensive they did not affect the entire country's reef systems at one time, and though variable, substantial recovery to pre-bleaching levels was seen within 5 years, in many areas indicating a high level of resiliency to bleaching events. Several factors are thought to be integral to this resiliency.

Fiji's reefs show great physical and species diversity and are spread over a large geographical area. Reservoirs of unaffected coral were always to be found somewhere in the archipelago.

While Fiji's sea water temperatures have reached or exceeded the bleaching threshold in most summers of the last 10 years, there is a sea water temperature range of 1.5^{o}C over the archipelago. This range provides areas where corals exist in lower temperature water, and appear to have escaped the mass bleachings.

In addition Fiji is remote from highly populated landmasses and large scale industrial pollution sources. There are threats to near-shore reefs from agricultural pollution, coastal development, and over-fishing, but there are extensive reefs areas unaffected by these.

As a result of combinations of these factors, corals have managed to survive the mass bleaching mortality events of 2000 and 2002 in habitats which appear to be conducive to minimizing the effects of bleaching. This allowed for the repopulating of affected areas more swiftly than may occur in more isolated reefs.

Conclusions

After 9 years of monitoring including the 2000 & 2002 bleaching events, Fiji's reef system experienced rapid coral re-growth in many areas.

Over the country, many reefs returned to pre-bleaching coral cover levels in approximately 5 years. Fiji corals can survive catastrophic events as long as they do not occur too often. A high degree of resiliency of the Fiji reef system as a whole is indicated, and is a cause for optimism.

There may be a case for special attention to preservation of remote yet connected reef systems such as Fiji to provide reservoirs of resilient corals in the face of the continuing global downturn in coral reef health.

Acknowledgements

Appreciation for the Global Coral Reef Monitoring Network (GCRMN) and Reef Check for initiating a co-operative project to train a network of survey teams who could report on coral reef health across the country. Many thanks to the Fiji Coral Reef Monitoring Network participants whose data is summarized in this report. Coordination for the project was provided by the Institute of Marine Resources at the University of the South Pacific and Resort Support, Fiji. The Coral Reef Initiative in the South Pacific (CRISP) provided funding for this project.

Abstract. Tools in the assessment of socioeconomic and governance factors for managing marine protected areas (MPAs) are continuously being developed. A standardized set of guidelines to conduct socioeconomic monitoring for collecting and analyzing socioeconomic was developed and dubbed as the Socioeconomic Monitoring Guidelines for Coastal Managers in Southeast Asia (SocMon SEA). SocMon SEA was employed to assess the dependence on marine resources, perceptions of resource conditions, perceived threats to marine resources and use levels at Binduyan Fish Sanctuary, a locally-managed MPA in Puerto Princesa City, Palawan Province, Philippines. Results of the survey indicate that almost half of its population is below 20 years old; nearly three quarters are migrants; a quarter reached high school level; and barely 12% belong to a stakeholder organization. These stakeholders perceived their natural resources to be in good condition. They also articulated their perceived threats related to cutting of mangroves, destructive fishing activities and pollution for beaches. These informative results indicate that SocMon SEA as a methodological tool was useful in generating relevant information in evaluating the current socioeconomic conditions in an MPA. Such demonstrates its potential for large-scale use in the Philippines and Southeast Asia due to its ease in field application and data analysis.

Key words: marine protected areas (MPAs), Socioeconomic Monitoring Guidelines for Coastal Managers in Southeast Asia (SocMon SEA), Binduyan Fish Sanctuary, Puerto Princesa City, Palawan Province, Philippines.

Introduction

Methodological tools in the assessment of biophysical parameters in marine protected areas (MPAs) have been fairly standardized. The same level of consensus is not yet reached in assessing the human dimension's socioeconomic and governance variables. In this context, 'Socioeconomic Monitoring Guidelines for Coastal Managers in Southeast Asia (SocMon SEA)' was developed. SocMon SEA is a standardized set of guidelines on how to conduct socioeconomic monitoring for coastal managers. SocMon SEA is intended to be a simple methodology for collecting and analyzing basic socioeconomic data useful for coastal management at the site level (Bunce and Pomeroy 2000). SocMon is a companion to the GCRMN Socioeconomic Manual for Coral Reef Management (Bunce et al 2003). Both the SocMon SEA and the GCRMN manual should be used together.

Understanding the socioeconomic context of any MPA is essential for assessing, predicting and managing coastal resource use. Without or with limited socioeconomic information, the coastal managers will be constrained in planning and managing their coastal resources. SocMon SEA is now being used in many parts of South East Asia to enhance understanding of the social, cultural, economic and political characteristics. Moreover, it helps in assessing the conditions of individuals, households, groups, organizations, and communities who use coastal resources and are affected by coastal management.

SocMon SEA was specifically employed in this Philippines' case study to: (1) establish baseline household and community profiles for monitoring and evaluation; (2) determine the importance, value and significance of resources and their uses; (3) build stakeholder participation; and (4) train researchers on SocMon SEA's field survey methods and data analysis. This paper presents some of the results generated at the Binduyan Fish Sanctuary, a locally-managed MPA situated in Puerto Princesa City,

Palawan Province, Philippines. One of the constraints identified in the management of this MPA site is the limited relevant socio-economic baseline information. Hence, from the management context, the SocMon was used as both a participatory and research tool to generate some of the desired sets of information.

Material and Methods

Methodologically, SocMon SEA involves a three-stage process (Figure 1). Advance preparation involves several activities including identifying the coastal stakeholders, identifying the study area, assembling a SocMon team, identifying the variables to be examined and obtaining government and stakeholder approvals. Data collection is at the core of the SocMon process, ideally consisting of 60 socioeconomic variables. It involves both secondary data analysis and primary data gathering. Report writing follows after data analysis. The results are then packaged and communicated to the relevant stakeholders.

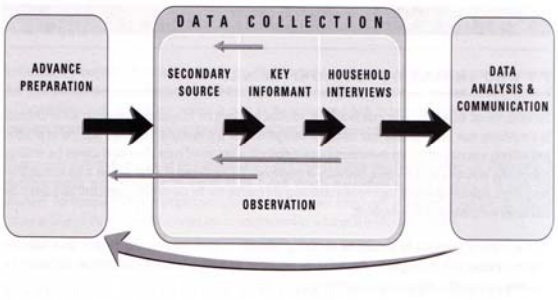

Figure 1. Major phases for conducting SocMon. (Source: Bunce and Pomeroy 2003)

Binduyan Fish Sanctuary, a locally-managed MPA situated in Puerto Princesa City, Palawan Province, Philippines, was selected as the study area (Figure 2 and Figure 3). Consisting of a corraline area, with associated mangroves and seagrass beds, it was declared as an MPA in 2002. Its reef area had about 48% live coral cover in 2004. In 2008, the live coral cover was assessed at 63%.

Binduyan is typical of most coastal fishing villages in the Philippines (Bernardo and Valientes 2001; Environmental Legal Assistance Center, Inc 2001; Office of the City Agriculturist. 2001). Founded in 1960, its land area covers some 8,968 ha. With about 1,200 people clustered in 193 households, there were an almost equal number of male and female residents. Its population is highly productive, given that 55% are below 20 years old. Barely 12% belong to stakeholder organizations. Migrant population now comprise nearly three quarters of the residents. Community members are heavily dependent on the fisheries. More recently, eco-tourism activities – such as island hopping and reef snorkeling – are being undertaken.

Figure 2. Location map of Puerto Princesa City, Palawan Province, Philippines.

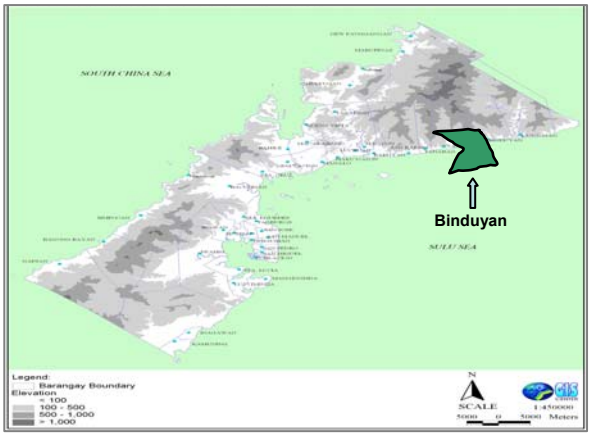

Figure 3. Location map of Binduyan Fish Sanctuary in Puerto Princesa City, Philippines.

The SocMon team assembled consisted of members from various institutional partners. Those who participated were representatives from a national government agency (Palawan Council for Sustainable Development Staff); a non-government organization (Conservation International-Philippines); a local academic institution (Palawan State University) and a local government unit (City Government of Puerto Princesa). The review of secondary literature, which was compiled from a variety of sources, was jointly undertaken by the SocMon team. Secondary literature consisted of biophysical, socioeconomic and governance information.

The SocMon team members collected primary data from two sources. The first set was obtained from the key informants. These were individuals who - because of their position, experience and/or knowledge - were able to provide insights into the larger population. The second source of information was from household/individual interviews. Important for understanding individuals'

perspectives, data were collected directly from the individual/household members. Only data from household/individual interviews are presented in this paper.

Results

Three key results are presented. These relate to the following socioeconomic variables: (1) perceptions of resource conditions; (2) perceptions of non-market and non-use values; and (3) material style of life of households.

Coastal residents generally perceived their resources to be in 'good' condition, with only very few individuals who perceived them in either 'bad' or 'very bad' condition (Table 1). They perceived their waterfalls to be in 'very good' condition with the highest mean rating at 4.21. They gave lowest ratings on seagrass, river/creeks, and upland forests with mean ratings hovering between 3.89 to 3.94.

Table 1. Perception of resource conditions. (n = 135)

Type of Resource	Perception Scores (%)*				
	1	2	3	4	5
I. Coastal					
1. Mangroves	2.3	2.3	10.5	59.4	25.6
2. Coral reefs	2.3	0.8	8.4	58.0	30.5
3. Seagrass		2.4	21.0	62.1	14.5
4. Beach	0.8	2.5	8.2	51.6	36.9
II. Terrestrial					
1. Spring	2.8	1.9	19.6	43.0	25.0
2. River/Creeks		3.4	25.6	46.2	24.8
3.Waterfalls	1.1	1.1	12.9	33.3	51.6
4.Ground Water	6.0	2.6	13.7	40.2	37.6
5. Upland forests		2.3	26.7	45.8	25.2

*Very bad – 1; Bad – 2; Neither good nor bad – 3; Good – 4; Very Good – 5

Resources are conveniently divided into coastal and terrestrial. Hence, their perception ratings may be aggregated by resource category. Coastal resource conditions had a mean rating of 4.09. Meanwhile, terrestrial resource conditions had a mean rating of 4.07. Standard deviations are relatively small at 0.46 and 0.52, respectively. Hence, both resource categories fall within the 'good' rating.

Factor analysis was undertaken to aggregate the responses of respondents. Rotated component matrix of the factor analysis reduced the perceptions on conditions of nine resources into four factors (Table 2). Those with asterisks are the ones that have high and logical factor loadings on each component. Respondents' perceptions on the conditions are almost similar for: (1) spring and river/creeks; (2) coral reefs, seagrass, beach; (3) waterfalls, ground water; and (4) mangroves and upland forests. The first three clusters appear logical, as similar resources are clustered together. The fourth cluster is interesting, as the respondents seem to view mangroves as not part of the coastal ecosystems. Rather, they treated the mangroves as more of terrestrial forests, similar to those found in the uplands. Some 73.3% of the variance in perceptions is explained by the four extracted factors.

Table 2. Rotated component matrix of the factor analysis of perception of resource conditions (n = 135).

Resource	Component			
	1	2	3	4
Mangroves	.537	.155	-.334	.438*
Coral reefs	.352	.601*	.024	.130
Upland forests	.013	.058	-.093	.855*
Seagrass	-.078	.867*	.114	.146
Beach	.394	.728*	-.251	-.241
Spring	.868*	.202	.087	-.020
River/Creeks	.830*	.053	.327	.020
Waterfalls	.220	-.020	.862*	-.208
Ground Water	.063	.510	.523*	.412

Residents valued their coastal resources far beyond their direct use values (Figure 3). Majority of the respondents perceived the coastal resources as more than products to be bought or sold in the market. Hence, the resources are significant to them on any of the following: (1) resources have value for its potential future direct and direct use (option value); (2) resources have value if it will be available for future generations to enjoy or utilize (bequest values) or, (3) value of knowing that the resource subsist in a certain condition whether it is utilized or not (existence value). Overall more than of two thirds of the respondents perceived that the coastal resources have value irrespective of whether it is used directly or indirectly.

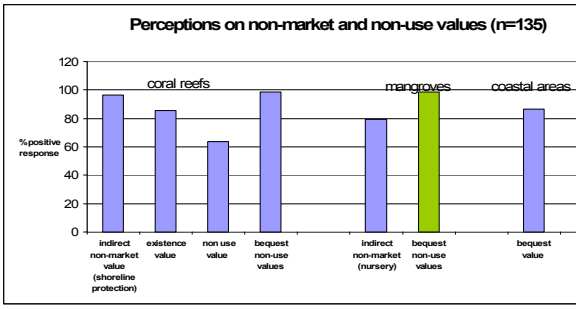

Figure 3. Perception of non-market and non-use values resource conditions. (n = 135)

Wealth is one of the most difficult indicators to measure in developing countries. Hence, 'proxy' variables are often used to determine the household level of wealth or income. 'Material style of life' is an indicator of the relative social status of a community household to indicate the level of wealth its members.

It involves assessing both the household construction materials and the household furnishings and electronics contained therein.

Houses of Binduyan residents are typical of rural coastal households (Table 3). Roof are either made up of any of these materials: (1) thatch/nipa (made of palm leaves) and tin/galvanized iron (GI) sheet; (2) outside structural walls consist largely of thatch/bamboo, brick/concrete and wood plywood; (3) wooden windows; and (4) cement or thatch/bamboo floors.

Table 3. Material style of life of households. (n = 135)

Parameter for Material Style of Life	Value	%
Type of Roof		
Tile	1	0
Tin/GI sheet	2	45.6
Wood/Plywood	3	0.9
Thatch/nipa	4	52.6
Thatch/bamboo	5	0.9
Type of outside structural walls		
Tiled	1	0
Brick/concrete	2	18.9
Wood/Plywood	3	18.9
Thatch/nipa	4	12.2
Thatch/bamboo	5	50.0
Windows		
Glass	1	7.9
Steelbars/grills	2	1.8
Wooden	3	67.5
Open	4	15.8
None	5	7.0
Floors		
Tile	1	2.6
Wooden	2	3.5
Cement	3	42.6
Thatch/bamboo	4	42.6
Dirt	5	8.7

Each of the responses was converted into numerical rating: in the case of the type of roof, for example, tin/GI sheet has a value of 4, while thatch/bamboo has a value of 1. As an instance for windows, a glass window has a value of 1, while a wooden window has a value of 3. Out of a lowest possible aggregate score of 5 (very high material style of life) and highest aggregate score of 20 (very low material style of life), the computed scores ranged from 8 to 18. This range was transformed into three categories: low, middle, and high. The aggregated ratings for 'material style of life' are as follows: low 30.4%; middle 36.3%; and high 33.3%.

Discussion

Community residents perceived that that the conditions of their terrestrial and natural resources are still generally in good condition. These community perceptions are largely consistent with biophysical monitoring of both coastal and terrestrial resources. They admitted, however, that there are continuing threats associated with development activities. Major threats to mangroves include cutting for household uses and clearing for human settlements. Threats to corals are mainly associated with illegal fishing activities, particularly the use of cyanide, compressor and dynamite. Threats to seagrass beds largely relate to fishing using dragnets and gleaning. The key problem with beaches is garbage dumping or solid waste disposal; other threats are development-related, such as pebble gathering/taking, sand quarrying and beach resort development. Perceived threats in order of decreasing importance were: cutting of mangroves; destructive fishing activities and pollution for beaches. To maintain the relatively good conditions of the natural resources, the threats identified must be properly mitigated with appropriate management actions/interventions.

The community members are aware of the benefits of the coastal resources beyond direct use values. They generally agree about the indirect value of the resources that are not traded in the market. They also put high value on future benefits or option value for future generation. The MPA's values for eco-tourism and aquaculture are now being given importance. For eco-tourism, related activities include diving, snorkeling and swimming. In the case of aquaculture, environment-friendly seaweeds farming are being promoted in the vicinities to augment the income of the community members.

The use of proxy variables – such as the material style of life – was an innovative part of the SocMon SEA methodology. In rural setting, wealth is one of the most difficult socioeconomic variables to measure. Through the SocMon process, we were able to approximate the relative level of wealth of the Binduyan households. Generally speaking, the economic strata of the household units can be arbitrarily classified into three groups: one third is wealthy; one third is middle class; and one third is poor. The local authorities are now aware of the economically-disadvantaged group to target for their future socio-economic interventions.

SocMon SEA was found useful in generating relevant information to evaluate the current socioeconomic conditions in MPAs. These include information on demographics, local perceptions, attitudes and values about natural resources. The results of the study are now being used in local development planning process specifically at the city and community level. Moreover, the SocMon SEA has recently been used in generating some socio-economic information of two coastal villages within Puerto Princesa City.

SocMon SEA has potential for between and across site comparisons, given the SocMon surveys undertaken in the provinces of Palawan and Batangas. It has also potential for large-scale use in the Philippines and Southeast Asia by virtue of its ease in field application and data analysis.

Acknowledgement

We would like to thank the NOAA for providing the grant for SocMon SEA training, primary data gathering and data analysis. The authors would like to thank also Dr Christy Loper of NOAA

for her technical assistance and coordination support, as well as Dr Robert S Pomeroy for spearheading the training.

Abstract. Central Sulawesi Province, Indonesia in the heart of the Coral Triangle with over 4,500km of coastline including the Banggai Archipelago, Togean Islands Park and several smaller MPAs. Since the Reefs at Risk study in 2000/2001 predicted high threat levels for most reefs in the Province, several survey and monitoring programmes have been supported by international, national and local sources. This paper summarises coral reef condition and socio-economic data over the period 2001-2007 in 7 of the 10 District/City areas, key conclusions and local initiatives. Based on the Global Coral Reef Monitoring Network (GCRMN) scale, the average condition is Poor, with reefs in Very Poor, Poor, Average and Good condition in all 7 areas but extremely limited areas in Very Good condition. Major impacts include coral mining, sedimentation, destructive fishing (including invertebrate collection.), increasingly severe overfishing, take of protected species and predation by *Acanthaster plancii*, with low awareness regarding many illegal and/or destructive practices. Initiatives include coastal/reef ecology, survey and conservation for undergraduates, community MPAs, COTs clean-up and habitat restoration. However the extent and scope of management efforts still needs to be greatly increased to reverse the destructive trends and ensure "Reefs for the Future" here.

Key words: Central Sulawesi, Reef status, Reef monitoring, Reef management

Introduction and Methods

Central Sulawesi Province, Indonesia in the heart of the Coral Triangle has over 4,500km of coastline and over 700 islands including the Banggai and Togean Archipelagos, with almost continuous fringing reefs, extensive barrier reefs, patch reefs and several atolls.

The Togean Islands National Park was declared in 2004 and there are several smaller national and local MPAs. Since the Reefs at Risk study in 2000/2001 (Burke et al. 2001) predicted high threat levels for most of the reefs in the Province, a number of survey and monitoring programmes have been undertaken using GCRMN methods: Reef Check (Hodgson et al., 2004); manta tow, Line Intercept and Point Intercept transects (LIT/PIT) (English et al., 1997) in 7 of the 9 Districts and in Palu City, with support from international, national and local sources (Fig. 1.).

Many of these surveys also collected socio-economic data, mainly using the KAP (Knowledge, Attitude and Perception) method (CRITC 2001) or livelihoods survey tools (STREAM 2002). Published survey data and official reports (listed under References) are supplemented with as yet unpublished data and information collected by the authors.

The data available was analysed for two geographical areas: the so-called "West Coast" facing the Makassar Straits and Sulawesi Sea, including the Donggala, Tolitoli and Buol Districts and the City of Palu, and the "East Coast" around the Gulf of Tomini and Gulf of Tolo, including the Districts of Parigi Moutong, Poso, Tojo Una-Una, Banggai Kepulauan, , Banggai and Morowali.

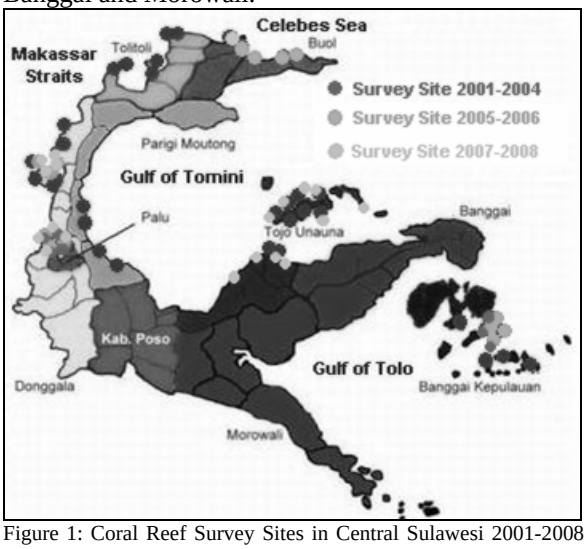

Figure 1: Coral Reef Survey Sites in Central Sulawesi 2001-2008 for which data was available for this study

West Coast: Makassar Straits and Sulawesi Sea

Tolitoli and Buol Districts form part of the Sulu-Sulawesi Marine Ecoregion (SSME) where Indonesia, Malaysia and Philippines have signed an agreement as basis for integrated sustainable management,. However so far there has been no involvement of regional (District and Provincial) Governments or stakeholders.

Where time series are available there has been little change in overall condition since 2004, though there is a slight downward trend. The average condition is Poor (11-30% hard coral cover), with highest coral cover generally observed near the reef crest except at Pasoso MPA where corals thrive to depths below Reef Check standards or even safe diving limits.

The most recent Manta Tow data indicating the range of coral reef condition by District and Reef Check/PIT data indicating hard coral cover at sites in this area are shown in Fig. 2.

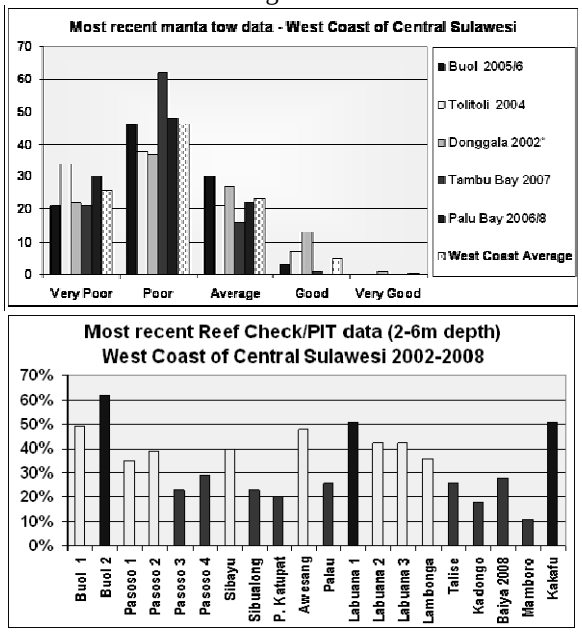

Figure 2: Most recent West Coast coral condition data, Manta Tow (above) and Reef Check/PIT (below)

Large fish are increasingly rare though some large demersal fish were seen in Buol. The Reef Check data from survey sites in the Makassar Straits and Palu Bay generally indicate very low populations of most commercial fish and invertebrate species.

KAP data from 2007 confirms this, with almost all fishers perceiving a fall in catch per unit effort (CPUE). In Tambu Bay, previously a source of fish for Palu City (Anonymous 2002) most fish sold is now from Kalimantan or the Gulf of Tomini (Anonymous 2007a)

Almost all marine species protected under the Law PP No. 7 1999 are found in the area and apart from the Coelacanth (recently discovered in Buol) all are exploited, most of them heavily. As an example, in Tambu Bay fishermen say the triton *Charonia tritonis* and napoleon wrasse *Cheilinus undulatus* are now fished out and turtles are increasingly rare; and all six species of Tridacnidae are collected in huge numbers and sold at low prices (cheaper than fish) in Tolitoli.

COTS attacks: the corallivorous Crown of Thorns starfish *Acanthaster plancii* is a major problem in all areas surveyed from 2004 onwards, a trend which was predicted from 2002 data (Anonymous 2002)

Coral mining: although illegal, massive corals are sold openly for around $10/m3. According to community members law enforcement personnel are often involved actively or in collusion

East Coast: Gulf of Tomini and Gulf of Tolo

Tomini Gulf data were available for Parigi Moutong and Tojo Una-Una, and Tolo Gulf data was from Banggai Kepulauan, whereas no data were available from Poso, Banggai, and Morowali Districts, meaning coral reef data for the Sulawesi mainland were limited with none for the Gulf of Tolo.

Banggai Kepulauan District comprises the Banggai Islands, and most coral reef data were from habitat and population surveys of the endemic Banggai cardinalfish, *Pterapogon. Kauderni*, there were no Reef Check indicator species data. However recorded observations and KAP study results indicate that overfishing is generally less severe than in the Gulf of Tomini or the West Coast. The abundance of fisheries produce has prompted the establishment of an industrial-scale fish processing plant at Biak in the Gulf of Tolo.

The average condition is (just) Average, with more Good reefs seen than on the West Coast (Fig. 3).

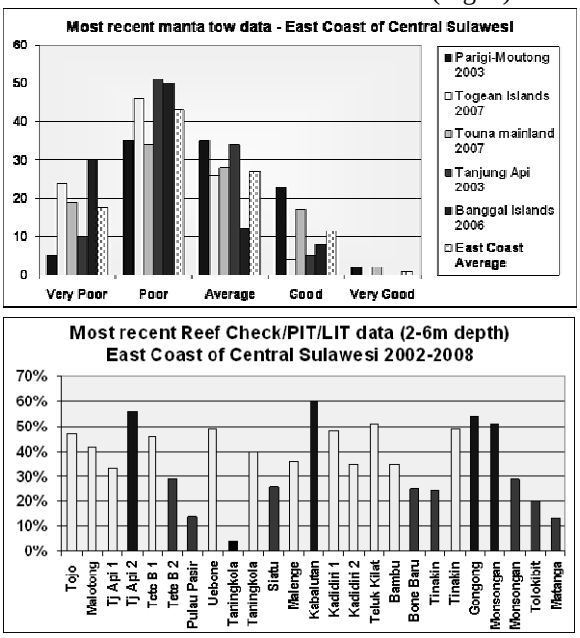

Figure 3: Most recent East Coast coral condition data, Manta Tow (above) and Reef Check/PIT (below)

Near to the shore, including the Togean Islands National Park, there is much severe damage due to

broadcast use of poisons (including cyanide), coral mining, gleaning etc, whereas bomb damage is generally worst at remote sites and mechanical damage when gleaning or harvesting invertebrates with crowbars especially abalone (*Haliotis* sp.) is often even more severe than the effects of better known forms of illegal and destructive fishing.

COTS: *A. plancii* is causing major damage at sites in Banggai Island (2004-2007) and was observed in high number at some sites in Tojo Unauna in (2008), other locations may be affected.

Ornamental fish trade: high in the Banggai Islands, increasing in Tojo Unauna and Parigi Moutong, as is the live reef fish trade which is prevalent in the area, with frequent use of poisons and mechanical damage.

Sedimentation is severe near larger rivers, high seasonal discharges seem to have killed some reefs near to estuaries, the remaining visible tips attesting to the recent nature of this phenomena. The majority of mangroves have been degraded or lost, according to a recent study comparing available historical data.

In most areas domestic garbage is a common sight, and in some areas severe eutrophication has been observed, especially near intensive paddy fields. However in the islands water quality is generally excellent, there is high marine biodiversity and despite extensive damage this area has several dive destinations with potential to expand, including reef conservation activities, "macro" photography and other specialty interests.

The process of establishing MPAs in Parigi-Moutong, Tojo Unauna and Banggai Kepulauan Districts has been facilitated by the communication of survey data to local stakeholders. Several de-facto reserves have evolved around marine tourism sites, often not without conflict.

General Trends and Threats

Some of the trends and threats observed across the Province include:

Coral condition monitoring: slight downward trend in coral condition; increased indirect impacts

Attitudes: KAP studies from 2002 and 2007 show growing community-level awareness regarding destructive fishing but little change as regards most other threats

Destructive fishing: bomb fishing: substantially reduced in some areas; poison fishing: reduced in some areas but increased in others, linked to the spread of the live and ornamental fish trades; other less-well known forms, especially related to invertebrate collection (abalone, clams etc), are often as damaging or even more so

Coastal abrasion: a growing problem in all areas, linked to the widespread coral mining & mechanical damage

Take of protected species: rife wherever economically worthwhile, sometimes due to ignorance but more often knowingly;

Overfishing: seems to be increasing

IUU fishing: many incursions by foreign vessels, mis/non-reporting of catch/cargo, etc

COTS outbreaks are occurring in all areas surveyed since 2004, causing substantial damage.

Recent initiatives and IYOR events

Initiatives since the presentation at the 10th ICRS in Okinawa in 2004 (Moore *et al*. 2004) have included:

Further dive/survey capacity building/training supported by the Sea Partnership Programme and Tojo Unauna Tourism Service.

The introduction of coastal ecology and conservation-related subjects into the curriculum of all local fisheries and marine undergraduate courses including field activities such as survey/monitoring and coral restoration trials

The establishment of several community MPAs (some proving effective) and the Togean Islands National Park (management to date ineffective with poor stakeholder relations)

Dive for Earth Day COTS control & reef monitoring (Reef Check, AWARE Fish Count, Coral Watch) in Palu Bay by YPH and STPL-Palu, supported in 2007 by Yayasan Reef Check Indonesia, in 2008 an IYOR event.

The establishment of the Tojo Una-Una Coral Triangle Centre (CTC) in February 2008 as a local response to the Coral Triangle Initiative (Fig 4.)

Figure 4: Declaration of the Tojo Unauna CTC in the Togean Islands by the District Head Drs Damsik Ladjalani.

Some IYOR activities have already taken place, however further events planned to celebrate the second IYOR in Central Sulawesi include:

Activities in connection with the Togean Festival and the Tojo Unauna CTC

"Fish homes" reef restoration in Palu Bay (Provincial Fisheries Service), Palu City and Donggala District (underway)

Biorock coral reef restoration training and application in Palu Bay (Provincial Fisheries Service) and Tojo Una-Una District (Sea Partnership Consortium and Tojo Unauna CTC)

Since 2004, a significant development is the promulgation of several national laws relating to coastal ecosystems, especially UU No27 of 2007 regarding coastal management, under which all activities which damage or destroy coral reefs are forbidden and most main threats to coral reefs are explicitly listed with heavy fines and prison sentences, including coral mining, at present possibly the number one direct threat to reefs in Central Sulawesi. However as far as the authors are aware no cases have yet been brought to court let alone resulted in conviction. At the local level, Provincial and District regulations for coastal management (PERDA Pesisir) and other instruments are in being drafted or even already promulgated, but similarly have yet to be (effectively) implemented.

Outlook for the future

Overall the outlook for reefs in Central Sulawesi is both better and worse than in 2004.

A positive point is the increase in awareness among stakeholders at community and government level including decision-making groups. However this is not always reflected in actions.

The improvements in the legal framework have yet to have a noticeable effect and law enforcement officials often seem to be among the least aware.

Government planning is beginning to be directed towards conservation and restoration and some local government authorities are beginning to implement programmes based on survey and monitoring data.

However the awareness of legislative bodies seems to lag behind that of the executive and in many cases have not ratified reef and other coastal system related budget items proposed by line agencies.

New threats are emerging. In particular, increasing threats from global climate change. Water temperatures range from 26-31°C, with 29-30°C being the most common, close to the upper tolerance limit for many coral species, though no significant bleaching has yet been recorded.

There is a long road ahead to ensure the protection of the reefs in good or average condition, stop or mitigate direct and indirect causes of degradation and restore damage. A major question is: can we increase the condition of our reefs and maximise their resilience to these new impacts, at a great enough scale and in time?

Acknowledgement

The authors wish to express their gratitude to all the people and institutions who have assisted the work on which this paper is based, especially since the 10th ICRS in Okinawa. In particular, the Network of Aquaculture Centres in Asia (NACA), especially the STREAM Hub in Indonesia; the Mitra Bahari (Sea Partnership) Program of the Department for Marine Affaires and Fisheries; many Provincial and District Government Agencies and other institutions in Central Sulawesi; Yayasan Reef Check Indonesia; and of course all the survey team members. Special recognition is due to those who helped make the production and presentation of this paper possible, especially Tonny Wagey, Jill Heyde, Ederyan, Akhdary Supu and our colleagues at YPH and the STPL-Palu.

Response of Caribbean Reefs to repeated Stress Events

L. Jones

National Environment and Planning Agency (NEPA), 10 & 11 Caledonia Avenue, Kingston 5. Jamaica

Abstract. In recent times, coastal ecosystems and specifically coral reefs have been experiencing varying degrees of stress from several sources. The incidence of natural phenomenons such as hurricanes and bleaching events has increased to the point where one or both of these events are guaranteed to occur annually. Coupled with effects of terreginous run-off and poorly planned coastal developments, the reefs of the region are constantly bombarded with less than ideal conditions. At present coral cover is still low at most sites assessed and has been for a long while.
In Jamaica Reef Check assessments indicating coverage ranging between 2% and 37% were recorded between 2001 and 2006. Results from bleaching assessments conducted during and after the 2005 event depicted up to 75% bleaching in some countries and varied levels of recovery. Data from long-term monitoring sites in Jamaica also produced results, which indicate that the reefs are to an extent able to survive and recover from the stress events. Given the increased frequency of stress events it is still unsure what level of recovery will be realized and the duration.

Key words: Caribbean, coral, stress, recovery

Introduction

The marine environment is the most important natural resource in Caribbean countries. Hurricanes, disease, climate change, population growth and overfishing have combined to exert enormous stress on reefs of the region. Terreginous run-off and poorly planned coastal developments result in the reefs being constantly bombarded with less than ideal conditions (UNEP 2008). Increased frequency and incidences of intense hurricanes, rising sea temperatures, coral bleaching, disease are now common dilemmas facing the islands (Fig. 1).

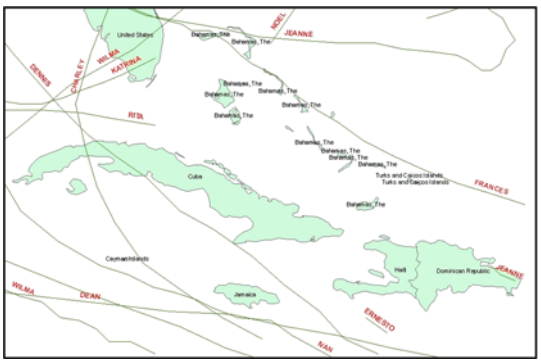

Figure 1 – Hurricane tracks 2004-2007

Current Status and Trends

The extent and severity of events varied across countries of the Northern Caribbean and Atlantic (NCA) node of the Global Coral Reef Monitoring Network (Fig. 2). As a result over the last quarter century some reefs associated with countries of the NCA node have experienced varied effects.

Figure 2 – Countries of the NCA node

Some corals were exposed to less stress and as a result were less susceptible to disease outbreaks. In the 2004-2005 bleaching outbreak between 50%-90% of coral colonies suffered partial to total bleaching. This resulted in a decrease of live coral cover in most islands and contributed to continued decline of the fishery of some islands (Souter and Wilkinson (Eds.) 2008).
In Bermuda the 2005 Atlantic hurricane season was the most active in recorded history with three tropical storms (Franklin, Harvey and Philippe) and two

hurricanes (Nate and Wilma). The increased frequency of hurricanes, repeated bleaching events and coral disease have had little impact on coral cover. Coral cover on the outer rim has been monitored since 1992 and has remained relatively stable over the 15 years (20.5% in 1992, 20.1% in 2007). Bermuda is the most northerly located country of the node. This may account for the fact that they do not experience prolonged periods of high water temperature which may cause bleaching.

The Bermudian fishery has experienced a shift towards pelagic species, particularly Wahoo (*Acanthocybium solandri*) and yellow-fin tuna (*Thunnus albacares*). Pelagic species now account for approximately 50% of the commercial finfish landings. This is in response to the ban imposed in 1990 on fish traps.

There is limited information on the current status of Bahamian reefs. Like other reefs of the region coral colonies are being pressured by proliferation of algae. Information from Rainbow Garden Reef suggests that bleaching, bio-erosion, and storm action reduced formerly discrete coral patches to rubble (Pante *et al*, 2007).

The Cayman Islands, specifically, Little Cayman recorded significant loss of coral cover between 1999 and 2004. There are however now signs of continued recruitment, decreased mortality and relatively stable coral cover. There has also been no increase recorded in the percent cover of fleshy macro-algae.

Episodes of coral bleaching were reported in the late 1980's, 1995, 1998, 2003, and 2005. The event was more pervasive in 2005 but did not result in mortality. From 1999 to present, there has been no overall change in the abundance or density of herbivorous fish species.

In Cuba, bleaching events of varying degrees were experienced in consecutive years during the period 2005 to 2007. Major stress events inclusive of frequent and intense hurricanes between 2001 and 2005, and microbial disease such as white plague, dark spot, white pox, yellow blotch and black band were common. Excessive algal proliferation due to scarcity of herbivores also affected several areas.

In the midst of these stress events a recovery of Diadema populations was observed along with resheathing on *Acropora palmata*. Reef Check surveys conducted in 2004 and 2005 indicated that hard coral mean percentage cover was 22.7% and 20.7% respectively. Atlantic Gulf Rapid Reef Assessment (AGRRA) surveys conducted in 2007 on the south and east of Golfo de Batabano provided live coral cover values of 9% to 50% for reef crests and 6% to 21% for reef zones.

The variation in reef status was again evident in the Dominican Republic. Reef conditions were dependent on the location and distance from the numerous river discharges. Reef Check assessments conducted between 2004 and 2007 showed that average coral cover ranged between 11.4% and 21.9%. Individual sites recorded percentages between 1.9% in 2005 and 34.4% in 2006.

The main problem on the reefs is the overfishing of several essential species such as *Strombus* sp., *Panulirus* sp., and fishes of the Serranidae, Lutjanidae, and Scaridae families. Additional threats include those of port development (construction and operations) at the Boca Chica reef which is the most studied reef site in the island. Increased sedimentation along the coast also threatens reef growth.

On the other half of the island of Hispaniola, Haiti, no comprehensive surveys have been conducted since 2003. At that time the reefs appeared to be in fairly good condition but, with no public sector involvement, the condition continues to degrade. Eutrophication, sedimentation, coral harvesting, pollution, and overfishing continue to be major issues affecting the coral reefs. At present the exportation of lobster and conch has been suspended by CITES. The unsustainable harvesting of wetland resources persists as mangroves are still being exploited for fuel wood, charcoal production and construction. Illegal coral harvesting continues and seagrass beds continue to be threatened by sedimentation and pollution.

The non-governmental organisation (NGO) Foundation pour la Protection de la Biodiversite Marine (FoProBIM) continues to monitor impacts and perform educational activities.

In 2005 the Turks and Caicos Islands like most of the region suffered a major bleaching event. As much as 50%-75% of coral colonies suffered partial to total bleaching. Reef Check assessments in 2004 and 2005 recorded averages of 10.6% and 5.9% respectively. In 2007 a more comprehensive assessment was conducted on 18 sites associated with the three major islands; Providenciales, West Caicos and South Caicos. Most sites assessed were dive sites with some level of legislative protection such as no anchoring and no fishing; depths between 12 and 60 feet were surveyed. On Providenciales live coral cover ranged between a low of 6.3% and a high of 38.8%. This is higher than the figures reported in 2004. Algal percentages ranging between zero and 46.3% were recorded. West Caicos and South Caicos recorded coral averages of 17% and 13% respectively.

Near-shore support systems such as seagrass beds and mangroves continue to thrive, however comprehensive monitoring of these systems is lacking. The country is currently experiencing a construction boom and all the associated pressures that arise from these activities.

Jamaican reefs continue to show variable cover by hard corals and other benthic substrates and have rebounded from the 5% hard coral cover recorded in the early 1990s to approximately 16%. Some sites have a relatively high and stable coral cover in percentages greater than the Caribbean regional average of 20% (TNC 2006). Overall hard coral percentage cover recorded from Reef Check surveys for the period 2004 to 2007 ranged between 2.2% and 37.5%.

The trend of algal dominated reefs is still visible on several reef systems across the island. This continued proliferation is due to the continued nutrient input and the absence of grazers. Overfishing has removed virtually all large predatory species, like sharks, snappers and groupers, and has sharply reduced the size of herbivores, namely parrotfish and surgeon fish. Notwithstanding of the myriad of environmental and biological factors affecting the reefs some have been able to maintain a relatively stable coral cover. Over the period 2001 to 2007 four sites (Ireland Pen, Bloody Bay, El Punto Negrilo and Little Bay) within the Negril Marine Park have been continuously monitored (Fig. 3). They have maintained overall coral percentages of 17.5%, 9.9%, 16.0% and 17.4% respectively.

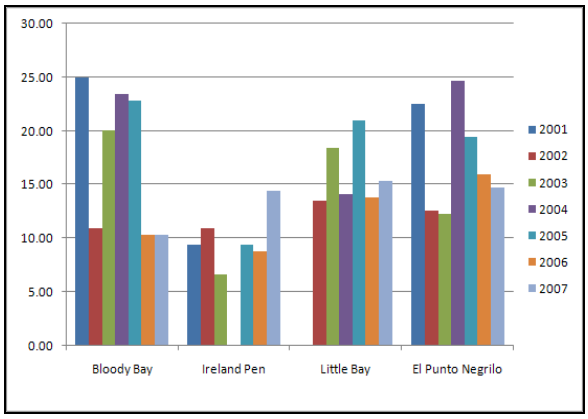

Figure 3 – Hard coral percentage cover on long-term monitoring sites in Negril, Jamaica: 2001 -2007

The region is now experiencing a new threat namely the Indo-Pacific lionfish (*Pterois volitans*). It has been reported in all the countries of the node except Haiti; this absence may however be due to a lack of monitoring. The presence of this invasive has the potential to further damage the already threatened fish population of the region and also affect coral health. This organism may also pose a threat to the highest economic earner of the Caribbean; tourism. In Jamaica they have been sighted on tourist dive sites and have also been encountered in fish pots at depths up to 60 feet.

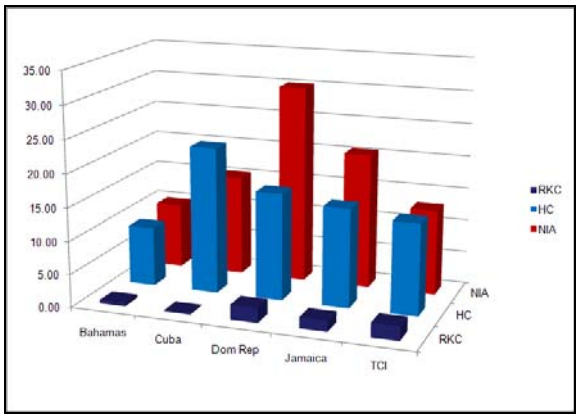

Figure 4 – Reef Check data 2004 – 2007showing average percentage cover for recently killed coral, hard coral and nutrient indicating algae

Discussion and Conclusion

The reef ecosystems of the region are comparable with respect to challenges encountered, coral cover, species distribution and composition (Figs. 1 and 4). While some reefs are indeed in serious trouble, others remain healthy and appear to be developing some resilience to the effects of natural forces and human activity. These reef systems appear to be able to recover from stress events such as high water temperatures, intense storms and prolonged sedimentation. This is evident on several Jamaican reef sites such as Little Bay, Westmoreland and Columbus Park, St. Ann which are sediment impacted sites. The degree of recovery is however dependent on time-span between stress events.

Hope for the reefs is also evident in the recovery of *Diadema antillarum* densities on some reefs along with *Acropora* sp. recruits. Current fishing practices however need to be changed to aid in the recovery.

In several countries, active monitoring is still not a standard government tool to manage the ecosystem. Governments need to develop strategies and methodologies for the assessment of the coastal area as a base for sustainable development. They also need to implement programmes and regulations to enhance coral resilience.

The region also needs to collaborate and formulate measures to combat the effects of the common problem of climate change and ocean acidification. A programme to deal with the lionfish invasion is also critically needed.

New insights into the exposure and sensitivity of coral reefs to ocean warming

P. Boylan[1], J. Kleypas[1]

1) National Center for Atmospheric Research, 1850 Table Mesa Drive, Boulder, CO 80305, USA

Abstract. Increases in coral bleaching events over the past 20 years are correlated with increases in sea surface temperature (SST). While SSTs have increased everywhere in the tropics, and coral bleaching events have occurred in all coral reef provinces, the frequency and intensity of coral bleaching events have varied considerably from region to region. Unless these patterns are random, we can derive useful information about why some reefs have been less vulnerable to increasing SST, and use this information to guide conservation efforts. Coral reef susceptibility to bleaching is a function of exposure to some stress (elevated SST) and sensitivity to that stress. To better characterize differences in coral reef vulnerability to increases in SST, we analyzed weekly SST records with coral bleaching records for reefs at the global scale. Our results indicate that variability of maximum SSTs is an additional factor that determines reef sensitivity to temperature increases, and taking this into account allows better predictions of coral bleaching in regions with low temperature variability.

Key words: bleaching, thermostat, SST, temperature, vulnerability

Introduction

The most commonly used predictor of when accumulated heat stress will cause coral bleaching is the degree heating week (DHW; (Liu et al. 2006)). The DHW index combines the severity of thermal stress (SST > 1ºC above the climatological maximum) with its duration over a rolling 12-week period. The NOAA Coral Reef Watch Program developed and maintains a very useful real-time bleaching predictive tool that calculates the DHW for reef regions worldwide. These calculations are based on twice-weekly satellite-derived SSTs at a spatial resolution of 50 km. DHW's are commonly used in studies examining the causal relationship between rising sea surface temperature (SST) and coral bleaching, but the method is known to over-predict and under-predict bleaching in some areas (e.g. McClanahan et al. 2007b) due to a range of factors associated with the scale and use of satellite data, to biological traits such as species composition.

When working with either historical or predicted sea surface temperature data, the temporal and spatial resolutions are much coarser; usually the data are weekly to monthly, and at best are gridded at 1x1° resolution. Previous studies that have used global climate model output to predict future bleaching frequency have used either a monthly SST threshold of 1ºC above normal maximum to predict bleaching (Hoegh-Guldberg 1999) or a degree heating month (DHM) index (Donner et al. 2005).

In order to develop a more generalized predictive tool for coral bleaching – one that can be used with more coarsely resolved past SSTs or model-projected SSTs, we examined ways to improve the DHW index toward predictions of coral bleaching. Our examination focuses on the concept of susceptibility, that is, not only a coral's exposure to high temperature event, but also its sensitivity to that exposure.

While it is clear that coral sensitivity to some maximum temperature varies regionally with differences in the climatological maximum, several studies have also suggested that corals from high-variability environments are more temperature-tolerant than those from low-variability environments (McClanahan et al. 2007a; Kleypas et al. 2008). In a rather crude analysis, (Kleypas 2006) found that the threshold of 1ºC above climatological maximum under-predicted coral bleaching in regions where the maxima varied little from year to year (e.g., in the eastern equatorial Pacific; Fig. 1), and that predictions improved if the threshold considered variability of maximum SST (Fig. 2). Here, we more closely examine whether coral sensitivity to elevated temperatures varies as a function of temperature variability.

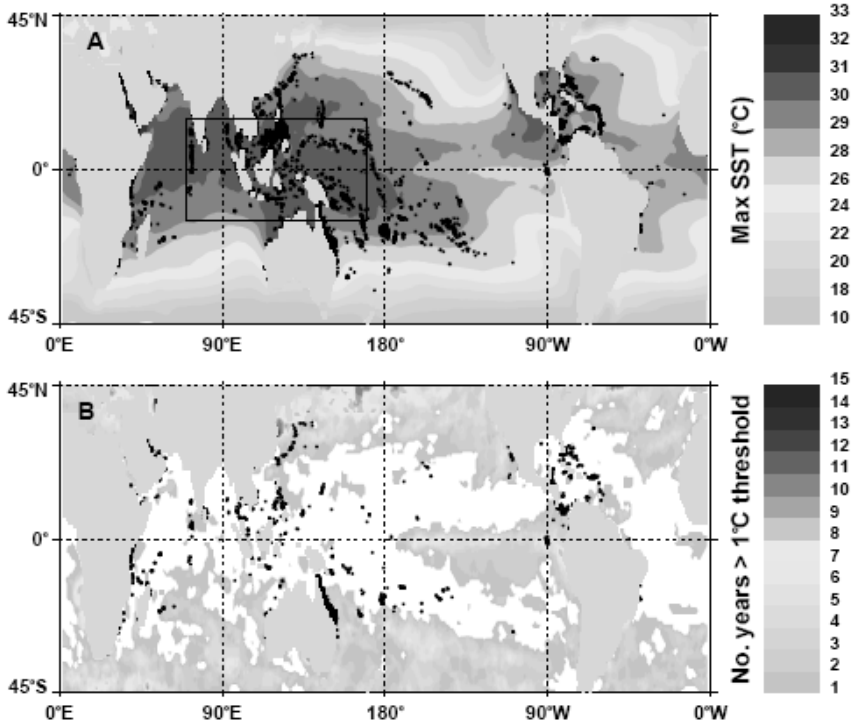

Figure 1: (A) Average annual maximum sea surface temperatures contoured showing locations of all coral reefs. (B) Number of years that the SST maximum exceeded the climatological maximum + 1ºC for at least one week. Black dots indicate reefs that have experienced bleaching (from Kleypas 2006).

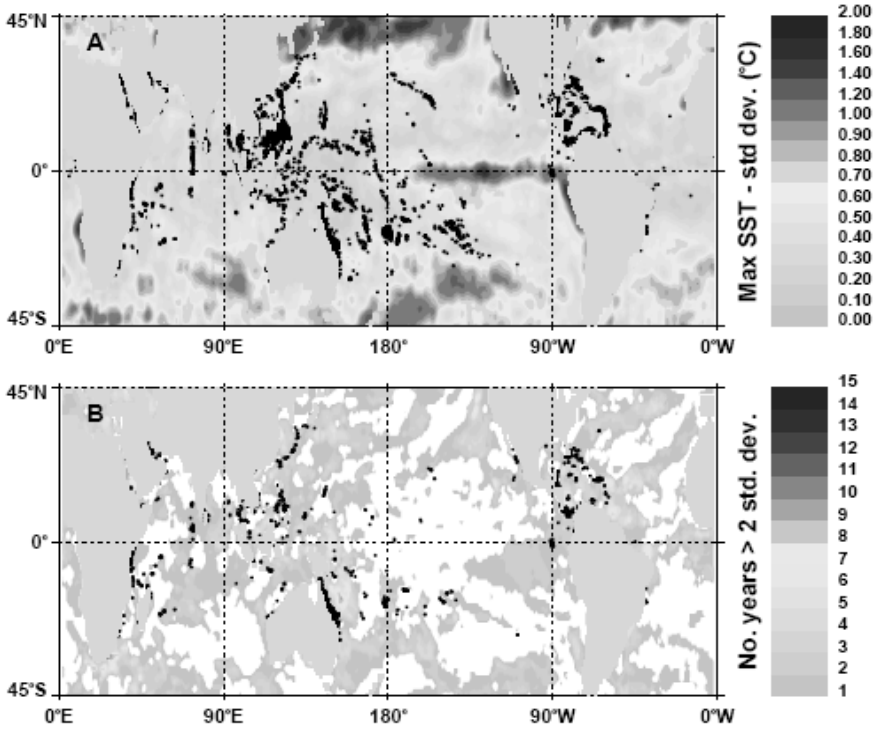

Figure 2: (A) Standard deviation of the average annual maximum sea surface temperature, showing locations of all coral reefs. (B) Number of years that the maximum exceeded the climatological maximum + 2 standard deviations for at least one week. Black dots indicate reefs that have experienced bleaching (from Kleypas 2006).

Methods

Data. Coral bleaching data were obtained from the ReefBase Global Bleaching Database (ReefBase-Project 2007). This data set is a compilation of mostly volunteer reporting of observations. NOAA's Coral Reef Watch Program has facilitated the ability to verify and qualify bleaching in areas where temperatures have exceeded certain thresholds, but coral bleaching has almost certainly been under-reported. The bleaching reports were summarized for each 1x1° cell, yielding a total of 516 unique reef locations that have experienced at least one bleaching event of any severity between 1982 and 2006.

SST data were obtained from the weekly Reynolds Optimally Interpolated SST (OISST) data set (Reynolds et al. 2002) for the years 1982–2006. The OISST has a spatial resolution of 1°x1°, and incorporates in situ observations as well as satellite-based observations.

Analysis. Using the weekly OISST data, the climatalogical maximum SST was determined for each grid cell as the average maximum for the first ten years of the OISST data (1982–1991). The standard DHW index (DHW_1), which uses an absolute threshold (1ºC above climatological maximum), and a modified DHW index (DHW_2) in which the threshold bleaching temperature is based on natural variability (for example, when SST > 2 standard deviations (SD) above climatological maximum), were then calculated for the entire OISST record. For DHW_2, we considered the variability of the annual maxima rather than that of the entire SST record. For both indices, we assumed that a bleaching event was possible once the DHW exceeded a designated threshold.

To account for the fact that bleaching is often observed some time after a temperature excursion, we assumed that a bleaching observation reported within 3 months following a predicted bleaching event was part of that event, and multiple observations within that 3-month time period were consolidated as one event. This was determined as the optimal time period for capturing most bleaching observations following a temperature maximum. Thus, a total of 725 bleaching events were identified for the 516 grid cell locations.

We determined "best fit" by maximizing the number of correct bleaching predictions (bleaching predicted and observed), while minimizing false negative (Type II error; bleaching not predicted but observed) and false positive predictions (Type I error; bleaching predicted but not observed). False positive predictions are particularly difficult to evaluate in this analysis because of the incomplete nature of the ReefBase data; that is, we do not have a good estimate of the number of bleaching events that occurred but were not observed or reported.

Results

Applying the standard bleaching index (DHW_1) with the weekly OISST data predicted 159 bleaching events over the 25-year period, but fails to predict 566 bleaching events (1.0ºC above maximum; Table 1). The number of predicted bleaching events that were not observed (438) is more than twice the number of correctly predicted bleaching events. If one assumes that, when bleaching occurred within a grid cell, at least one report was made and included in the ReefBase dataset, then the DHW_1 method correctly predicted bleaching 14% of the time [% correct = number of correct predictions/(total number of correct + incorrect predictions)]. If the temperature threshold is lowered to 0.7°C, then the method correctly predicts bleaching 19% of the time.

Table 1: Comparison of DHW_1 versus DHW_2 predictions of coral bleaching. Bold rows are predictions using the standard threshold (DHW_1), and the best results when using standard deviation of the annual monthly maximum (DHW_2).

1.5	35	690	81	4.3	2.5	189	536	374	17.2

DHW_2 performed best (20.4% correct predictions) using a 2.0 standard deviation threshold. 308 bleaching events over the 25-year period were correctly predicted, 417 bleaching were not predicted, and 788 events were predicted but not observed (Table 1). The % correct predictions dropped off at higher and lower standard deviation thresholds.

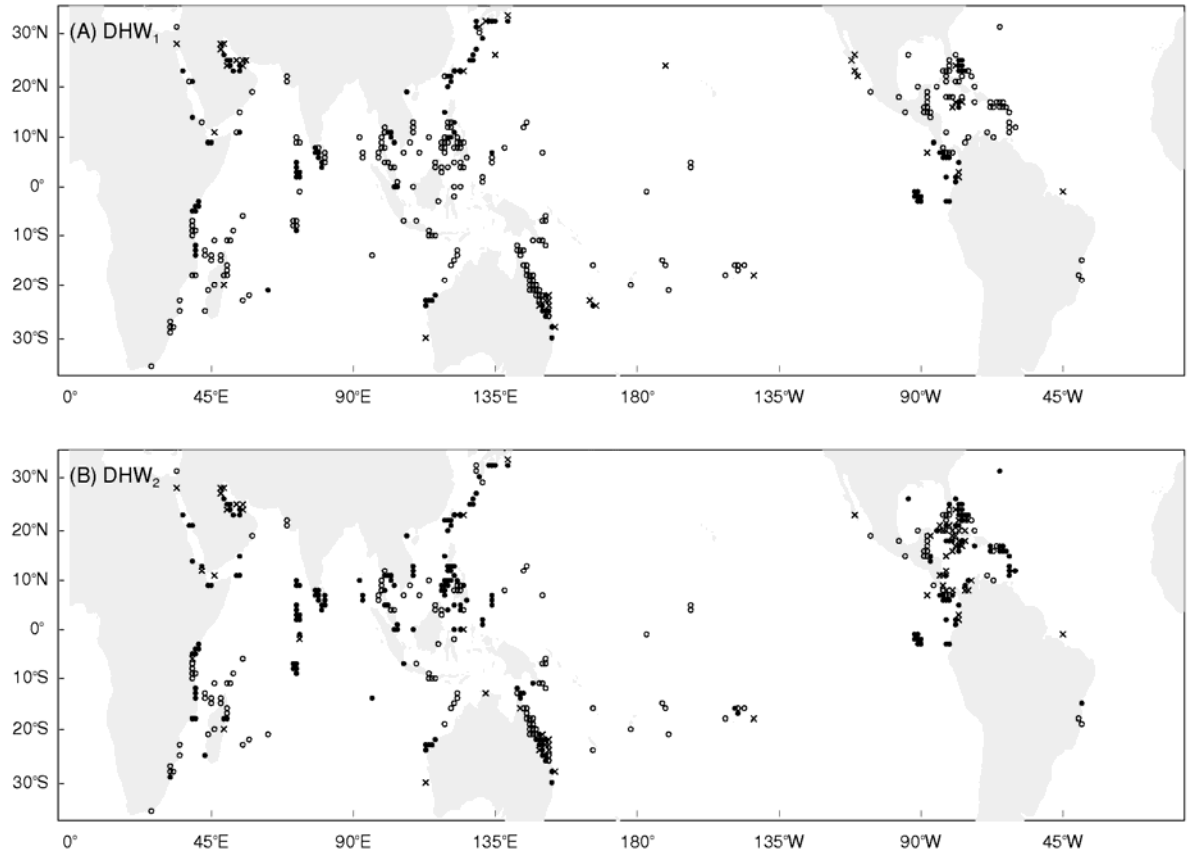

Figure 3: (A) DHW_1 predictions for 1997–1998. Solid black circles indicate a match: bleaching was observed where it was predicted. White circles indicate where bleaching was observed but not predicted (Type II error). The X's show locations where bleaching was predicted but not observed (Type I error). (B) DHW_2 predictions for 1997–1998.

Discussion and Conclusions

This rather simple analysis illustrates that neither method predicts bleaching well, but it does suggest that natural variability of the annual maximum SST is a factor that determines regional thresholds to bleaching. The most obvious error in both methods is the failure to predict bleaching when it occurs (Type II). The DHW_2 method seems to do a slightly better job at predicting the observed bleaching events. Both methods suffer from high Type I errors, such that bleaching is predicted much more often than it is observed. This over-prediction can occur for two reasons: 1) the coral reef communities did not bleach (a true Type I error); or 2) at least some bleaching events were not reported (and indeed, were probably not even observed) and thus were not included in the ReefBase data set. Thus, the number of over-predicted reefs is almost certainly less than shown here.

The distribution patterns of the correctly and incorrectly predicted bleaching events reveal a potential bias in the DHW_1 method in that it does a better job in high variability regions such as at higher latitudes and in upwelling regions (compare Figs. 1 and 2 with Fig. 3). The DHW_2 method seems to do a better job across regions, and successfully predicts bleaching events in regions with low SST variability (e.g. equatorial regions; Fig. 3). This implies that current bleaching predictions underestimate bleaching in low variability regions, such as in the western Pacific warm pool. It also implies that the conditioning of corals to bleaching is not only a function of the maximum temperatures that they are accustomed to, but also the variability in those maximum temperatures. Fig. 4 presents a clustering of coral reefs based on SST minima, maxima, and variability. We propose that these reef clusters have different thresholds to changes in temperature

extremes and variability, and that bleaching indices should take into account these differences. Finally, many other factors besides SST affect the bleaching thresholds in corals, such as solar radiation (Brown, Dunne 2008), mixing (Nakamura, Yamasaki 2005; Fabricius 2006), community structure (McClanahan et al. 2005), and clade-type of the zooxanthellae symbionts (Baker 2003; Berkelmans, van Oppen 2006; Jones et al. 2008). Like SST patterns, these variables also vary from region to region, and many have been shown to be important factors that contribute to regional variations in vulnerability to coral bleaching (McClanahan et al. 2007a; Maina et al. 2008).

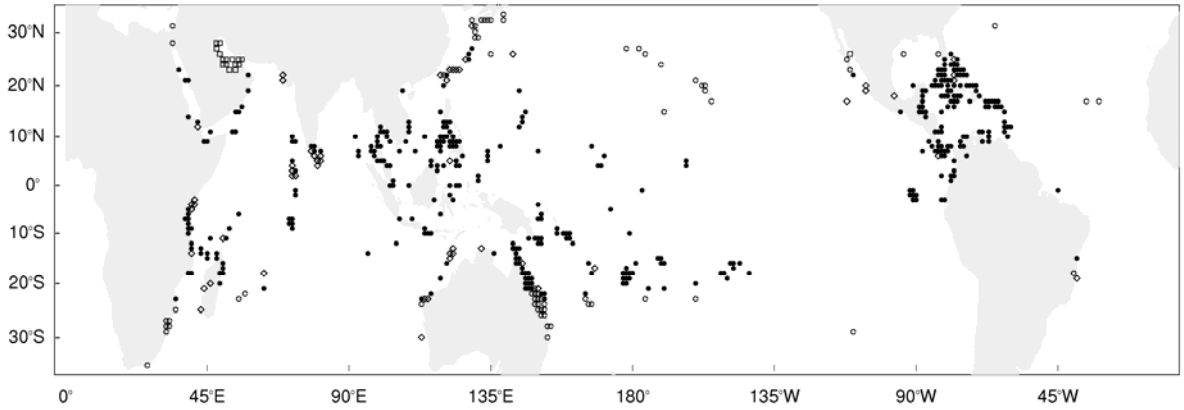

Figure 4: Reefs with common temperature characteristics, based on the minimum, maximum and variance of SSTs from the weekly OISST data (Reynolds et al. 2002).

[3] Principal Chief Conservator of Forests, A & N Islands, Van Sadan, Port Blair-744102, A & N Islands (India)

Abstract Andaman & Nicobar Islands, located in the Bay of Bengal off the eastern coast of India, are one of India's four major sites with coral reefs, mostly fringing types. The survey carried out by the UNDP team along with experts from India in 2001 recorded 197 species of corals in the Andaman group against 179 species reported earlier by Pillai (1983) for the entire Andaman & Nicobar Islands. The survey done by Kulkarni and Saxena (2002) for 24 coral reef sites identified under a coral reef monitoring action plan showed the distribution, status of health and mortality of corals. The Tsunami that struck these islands on 26th December 2004 led to vast destruction of coral reefs mainly due to geo-morphological changes resulting in uplifting and exposure of reefs in the northern islands and submergence in the southern islands A rapid assessment done by the NGO Reef Watch in 2005 showed that there was overall 20% mortality in Andaman group of Islands while in Nicobar group of Islands, up to 80% mortality was observed. The present study is based on the survey being carried out at different coral reef sites to monitor the recovery processes. The initial results show not only recovery but also changes in the distribution pattern of corals.

Key words: Tsunami, Live coral cover, Fringing Reefs, Soft Corals, Sedimentation

---

Introduction

The Andaman and Nicobar Islands (A & N Islands) constitute one of the hot spots of the biodiversity in India and exhibit a variety of ecosystems such as tropical forests, mangroves and coral reefs. They consist of about 570 islands of varying sizes and are the largest archipelago system in the Bay of Bengal. They are located latitudinally between 06º 45' N to 13º 41' N and longitudinally between 92º 12' E to 93º 57' E. Their rotal geographic area is 8249 km^2 and the length of coastline is 1962 km. Islands north of 10º N latitude belong to Andaman group of Islands and those south of 10º N latitude fall in Nicobar group of Islands. Only 38 islands are inhabited of which 12 belong to Nicobar group (total islands = 24).

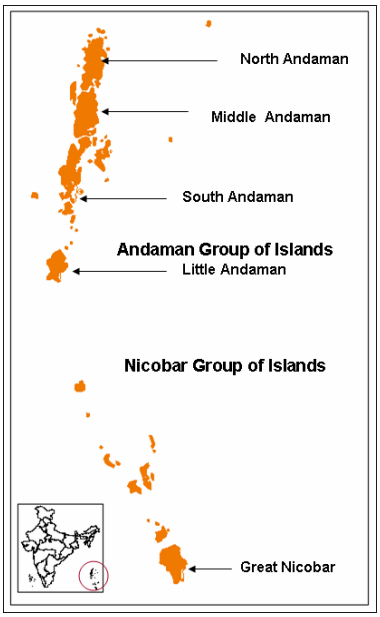

Fig. 1: Location map

Coral Reefs in A & N Islands

Coral reefs of the A & N Islands are highly diverse and reefs cover about 2000 km^2 i.e., 6% of the total

continental shelf of these islands, mainly as fringing reefs. A barrier reef of about 320 km length with 4 m deep lagoon has been reported on the western side of South and Middle Andaman Islands. It is separated by an 80 m deep channel. The common coral genera contributing to the reef formation in these islands are *Acropora, Montipora, Pocillpora, Porites, Gonopra, Favia, Echinopora, Fungia, Milleporina, Hliopora* etc.

Pre-tsunami status

The A & N Islands have the richest coral fauna among the four major coral reef sites of India (the other three sites being the Lakhsadweep, Gulf of Mannar and Gulf of Kutch). Alcock (1893) during his visit to Port Blair in 1888 gave a brief description of reefs here and also pointed out the adverse effect of silting in the inshore waters on coral growth. Sewell (1922) described the morphology, community ecology and formation of the reefs of Nicobar. Scheer studied reefs of Great Nicobar and Tillongchang islands. Scheer and Pillai (1974) gave an account of corals of Nicobar Iislands. Pillai (1983) reported 135 species belonging to 59 genera and Tikedar et al., (1986) reported 179 species belonging to 61 genera. A recent survey by a UNDP-GOI team who covered selected sites in the Andaman group recorded 197 species of stony corals and estimated the total number of stony coral species to be 234 in Andaman group of islands only (Turner et. al. 2001). Kulkarni and Saxena (2002) studied the status of coral reefs at 24 sites distributed over both groups of Islands under the programme of the Indian Coral Reef Monitoring Network (ICRMN). Wafar (1986) estimated the reef area of the Andaman Islands to be 11,000 km2 and that of Nicobar Islands to be 2,700 km^2. Nayak et al. (1994) estimated the total reef area to be 953.3 km^2 using remote sensing. Later, Turner et. al. (2001) estimated the reef area of Andaman Islands using remote sensing data, to be 11,989 km^2.

Post-tsunami studies

The Tsunami that struck these islands following a massive earthquake on 26th December 2004 caused heavy destruction not only of life and property but also of ecological resources. Reefs were damaged extensively both in Nicobar group as well as in northern islands of Andaman group. No detailed study on impact of Tsunami was carried out, only a few rapid assessments of damage to reefs. The study based on remote sensing data carried out in 2005 by the Space Application Centre (SAC), Department of Space, revealed that the tsunami caused two main types of damage to reefs- (i) total erosion or breaking up of reefs, and (ii) deposition of sand, mud and detritus on reefs. The report further revealed that the total loss (erosion) of coral reefs in the Andaman Islands was 22978 ha and in the Nicobar Islands it was 17180 ha. Reef Watch Marine Conservation made a rapid survey of selected islands in 2006 and reported that reefs in the North and Middle Andamans suffered mainly because of uplifting of land and exposure of reefs. The damage was less severe (about 20%) in reefs around South Andamans, but it was heavy in Nicobar group of Islands. The present paper deals with the assessments being done in details on selected representative sites in major island groups of A & N Islands.

Methods

The survey was carried out for Northern group of Andaman Islands in the year 2006 and for Southern Andaman and Nicobar group of Islands in 2008. The survey methods used included LIT (Linter Intercept Transect), Manto Tow and species diversity and area estimation in exposed reefs.

Results and discussion

The damage to coral reefs took place as a result of two events that occurred on 26th December 2004- the first one being the massive earthquake with intensity of 9.3 Richter scale causing geo-morphological changes in these Islands. The second was in the form of a giant tsunami wave. The earthquake resulted into uplifting of land by more than 1 m in the North and Middle Andamans and subsidence of land by more than 1 m in the Nicobar group of Islands. This led to exposure of reefs in the northern Islands of the Andamans where mortality ensued due to exposure of reefs while in the Nicobar group of Islands the damage was due to wave action. Many corals were uprooted, broken and turned upside down. Moreover, a lot of sediments was mobilized by wave action and currents, leading to smothering of corals.

North Andamans

The islands studied included Landfall, East, Smith & Ross, Aves, North Reef and Interview Islands. Significant mortality was observed in all the aforementioned Islands except in Avis Island. Following is the Island-wise account:

Landfall Island: Most reefs of Islands were totally exposed. Dead corals constituted of about 85 % of the reef area. *Acropora* constituted 65 % of the coral diversity, the species recorded included *A. florida,*

A. cytheria, A. monticulosa, A. humilis, A. palythoa, A. palifera and A. hyacinthus. Massive and sub-massive corals constituted about 20% and major genera were *Heliopora, Pocillopora verrucosa, P. eudoxyi, Fungia, Goniastrea, Favites, Porites lutea* and *Montipora.*

Fig. 2: Landfall Islands- exposed reefs

East Island: Like at Landfall Island, most of the corals were exposed and dead. Mortality was above 70 % and *Acropora* constituted 50 % of species. Massive and sub-massive corals constituted 20 %. Eight *Acropora* species (same as at Landfall Island), *Platygyra pini, Ctinactis echinata, Hydnopora rigida, Pocillopora damicornis, P. verucosa, Pocillopora euidui, Hydnopora macroconus, Symphyllia radians and Porites lichen.* were recorded.

Fig. 3: East Island

Smith & Ross Islands: Pre-Tsunami assessment by Kulkarni and Saxena (2002) showed live coral cover of 54 % to have declined to 3 %. Earlier dominant species were *Acropor*a (45%), *Porites* (16%) and *Montipora* (9%). After the tsunamic, *Porites* (49%) dominated followed by *Favites abtidia* (21%) and *Pavona* (18%).

Aves Island: Not much damage was recorded at this island. Pre-tsunami records showed live coral cover to be 62% and a slight decline to 50%. Earlier *Acropora* constituted 40% followed by *Porites* (23 %). After the tsunami, *Acropora* constituted 83 % and *Porites* 16 % of the community.

North Reef: This was one of the best reef sites of the Andaman Islands. Reefs suffered here heavily due to uplifting and exposure of submerged land. Live coral cover which was 74% earlier declined to 13%. *Acropora* dominated the live coral (77 %).

Interview Island: Reefs were exposed. Pre-tsunami live coral cover was 68%. post-tsunami the dead coral cover was 80%. Massive and sub-massive coral dominated (70%) and 42 species were recorded. *Diploastrea heliopora* dominates the sub-massive species.

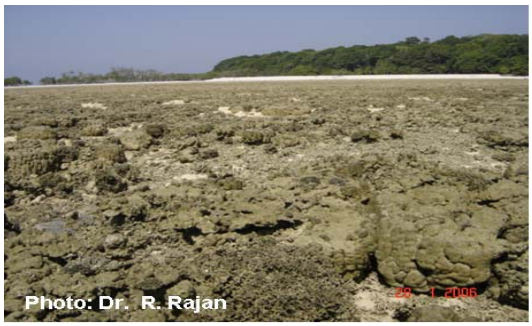

Fig. 4: Interview Island

South Andamans

In the South Andamans, seven Islands of the Mahatma Gandhi Marine National Park were studied which included Alexendra, Belle, Baot, Chester, Grub, Snob and Redskin.

Fig. 5: Mahatma Gandhi Marine National Park

Details of status of coral reefs in pre and post tsunami period are given in Table 1.

Table 1: Status of coral reefs in MGMNP

Island	Present Status	% Live Coral	
		Pre-Tsunami	Post Tsunami
Alexendra	Degraded, mostly Boulders	30 %	10-15 %
Bellie	Highly degraded, Massive corals	N. A.	< 10 %
Boat	Highly degraded, Massive corals	16 %	<10 %
Chester	Degraded, mostly Boulder	N. A.	40 %
Grub	Healthy, mostly branching	42 %	Around 60%
Redskin	Degraded, Mostly boulders, soft corals also present	33 %	20 %
Snob	Highly degraded, Massive corals	N. A.	20 %

Al though the tsunami did affect the reefs, the effect was not very pronounced. The reasons for degradation of reefs in this Marine National Park are mostly local factors that include high sedimentation rate, turbidity and oceanic currents. Corals were in good health around Grub and Chester but not at other islands.

Nicobar Islands

Heavy destruction, but also recovery was observed. Impacts were caused by strong tsunami waves as these islands were very near to the epicenter of the quake, as well as the heavy siltation caused due to oceanic currents.

Car Nicobar: High mortality (70 %). Live coral only 10 % while in 2003 live coral cover was above 70 %. Some reefs were totally destroyed up to a depth of 20 m. Some patches in shallow waters had survived.

Teressa: Less damage with dead corals at 37 %. Live coral cover was 34% and soft corals constituted 14.3%. *Montipora* was the most common genus (21 %), followed by *Porites* (6 %) and *Pocillopora* (6 %). Other species included *Acropora and Goniastrea.*

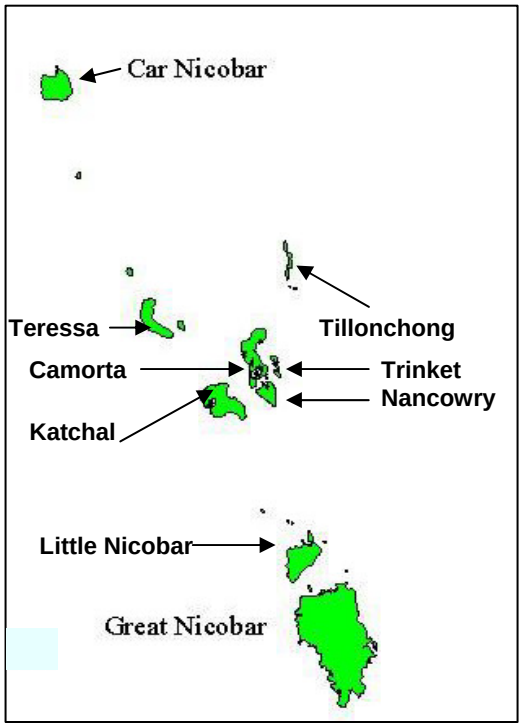

Fig. 6: Nicobar Islands

Camorta: Heavy damage. Dead corals extended over 80% of reef area, live coral on 7 %. Soft corals formed 4 % of total live corals. *Favites* was the most common genus (3 %), followed by *Porites* (2 %), *Siderastrea, Platygyra and Favia.*

Katchal: Signs of recovery. Dead coral covered 49 % of the reef area. Live coral cover 24 % and of this soft corals 12 %. Among live corals, *Heliopora* dominated with 22 %. Other genera include *Montipora, Pocillopora, Fungia and Symphylli.*

Trinket: Dead corals covered 62 % of the reef area and live corals only13 %. Soft corals only in some pockets. *Platygyra* was the most common genus (4.5 %), followed by *Acropora (4* %) and *Porites* (2 %). Other present genera included *Montipora, Goniastrea, Pocillopora and Heliopra.*

Nancowry: better live coral cover (39%) of which 10% was soft coral. Dead coral cover only 13%. Of the live corals, *Pocillopora* dominated with 12 %, followed by *Porites* (6%), *Echinopora* (5 %) and *Favites* (4.5%).

Little Nicobar: High mortality due to sedimentation and wave action. Live coral cover less than 10%.

Great Nicobar: More than 70 % of corals dead. Maximum damage (80 %) due to direct impact of Tsunami and 20 % damage due to sedimentation. Prior to Tsunami the live coral cover as assessed in 2003 was about 70%, post-tsunami is had declined to 20 %.

Invertebrates, Communities, and Reef Health in Airai, The Republic of Palau

A. H. Kitalong[1]

1) The Environment, Inc. P.O. Box 1696, Koror, Palau 96940

Abstract
During 2006 to 2008, a women's group studied the distribution, densities, sizes and harvest rates of edible invertebrates in southeast Babeldaob. Replicate transect lines, mobile GPS tracking units and traditional harvesting methods were used. Women covered a mean area of 2,520 m^2h^{-1} or 0.25ha h^{-1}. The mean CPUE for weight for all invertebrates collected was 2.4 kg $w^{-1}h^{-1}$ and the mean CPUE for weight for all invertebrates per hectare was 6.2 kg $w^{-1}h^{-1}ha^{-1}$ and differed significantly between sites. Low densities of *Hippopus hippopus* and *Holothuria scabra* were found. Low densities of *Tripneustes gratilla* may indicate a potential collapse in this fishery. Spawning of wild *Tripneustes gratilla* was observed in April 2007. Small and patchy populations were measured at finer spatial and temporal scales with input from resource users to better estimate and detect change in populations. One market sold a mean weight 1345 kg of selected invertebrates between 2000 and 2007. Airai State conservation officers are working with research, enforcement and community partners to manage these resources. Key invertebrates are potential indicators of reef health. These results can be used to set size limits, threshold densities of specific species and seasonal and site closures for specific sites.

Key words: Invertebrates, women, harvest, effort, management.

Introduction

Overfishing, pollution, habitat loss and global warming threaten fisheries worldwide. *Tridacna* clams are on the UN's red list of endangered species (IUCN 1983). *H. hippopus* is sensitive to elevated seawater temperature; mass mortality occurred in the Philippines during the 1998 ENSO event (Blidberg et al. 2000). *Holothuria scabra* is one of several prized sea cucumbers used as food, medicine and as an aphrodisiac. All *Tridacna* species and the sea cucumbers, *H. scabra* and *Actinopyga miliaris* are banned for export in Palau; *Tridacna* spp. are produced in hatcheries in Palau and the region (Heslinga et al. 1990). The gonads of *Tripneustes gratilla* were over harvested and the fishery collapsed in the Philippines (Juninio-Meñez et al. 1998). *Stichopus vastus*, an edible sea cucumber with regenerative properties and *Lambis lambis*, the culturally significant spider shell are declining in numbers. Women play a critical role in nearshore fisheries (Matthews and Oiterong 1991, Lambeth 1999). Our objectives were to work with a women's group in Airai to determine relative abundance, distribution, size and catch efforts for populations of key invertebrate species; share the results in the community; and discuss management options.

Materials and Methods

The Republic of Palau is the westernmost archipelago of the Caroline Islands in Micronesia that lies within latitudes 8°12' to 2°48' N and longitudes 131°07' to 134°44' E The study site is located in Airai State in southeast Babeldaob, the largest island in Palau (Fig.1).

Figure 1: Study sites (West, South, East) in Airai State, Southeast Babeldaob, Republic of Palau (Source: PALARIS).

Three sites along the West, South and East coasts of Airai (Fig. 1) were surveyed over a 34 day period from November 2006 to April 2008. At least three 50m transects were set 100m apart and parallel to the reef covered a minimal area of 750m^2 at each site for the key invertebrates optimizing overlapping habitats. Seagrass density and canopy height was measured within 0.25m^2 quadrants at either 4m, 5m or 10m intervals along the transect line; invertebrates were quantified within 5m of the transect line. The line intercept technique was used to quantify coral cover at the West site. Invertebrates were counted, measured to the nearest 0.1cm, and all but the unharvested embedded clams were weighed to at least the nearest 0.1 kg. The wet weight of harvested clam meat and the shell length were measured. Weight and lengths for *Tridacna crocea* and *T. maxima* where combined as embedded clams for this study as women did not distinguish between them in the field. Sea cucumber measurements are complicated because they change shape and retain water and sediment (Preston 1993). In this study, sea cucumbers were weighed and measured after sand and excess water was removed and if contracted, they were left few minutes before length was measured. The taxonomy of the Genus *Actinopyga* is under revision: the local name "cheremrum" represents several species. However we are referring to the smallest species in this genus with a variable coloration. The total weight of sea urchins was measured because they are sold unprocessed. Photo-documentation was conducted during the study.

The area covered during traditional harvesting was quantified using an "in-water" tracking device designed by Coral Reef Research Foundation which was a modified PVC waterproof casing that can a small GPS unit can be inserted and sealed with an screw top, airtight lid. An extended PVC pipe is attached to the device that has a foam float for buoyancy. A Garmin GPS unit was set to track position at 15 sec intervals. The device was either tied onto a person or a collecting basin. Data was downloaded, analyzed and mapped using ©Arcview software. Women searched a mean width of 4m and harvested singly or in groups. Individual and group catches were quantified. The non-parametric Kruskal-Wallis Test was used to test the null hypothesis that the CPUE for numbers (ct $w^{-1}h^{-1}$), the CPUE for weight (kg $w^{-1}h^{-1}$), the CPUE for weight per hectare (kg $w^{-1}h^{-1}ha^{-1}$), size and densities, did not differ significantly between the 3 sites. The Rank Sum Test was used to compare 2 sites (Ambrose, Ambrose 1987). Results were presented to over 250 people in the Airai community in a series of power point presentations. Concerns and comments were recorded and summarized.

Results

Seagrass Density and Substrate Cover

A total of 189 0.25m^2 quadrants were placed along transects at the West (n=72) South (n=73) and East (n=44) sites. The mean density for all seagrass species (plants 0.25/m^2) at each site was as follows: East: 3.1 (sd=4.4); South: 1.3 (sd=2.8) and West: 1.1 (sd=2.1). For all seagrass species, the mean height (cm) at each site was as follows: West: 13.9 (sd=12.3, n=134); South: 12.4 (sd=11.2, n=262); East: 9.2 (sd=5.3, n=381). The mean densities (plant 0.25/m^2) for each species at each site were as follows: West: *E. acoroides* 1.5 (sd=1.9), *T. hemprichii* 2.7 (sd=2.9); *C. rotundata* 0.3, sd=1.1); South: *E. acoroides* 1.4 (sd=1.7), *T. hemprichii* 3.2 (sd=4.6); *C. rotundata* 6.4 (sd=6.1); and *Syringodium isoetifolium* 0.2 (sd=0.8); East: *Enhalus acoroides* 4.1 (sd=3.2); *Thalassia hemprichii* 1.5 (sd=2.2); *Cymodacea rotundata* (6.4, sd=6.1); and *S. isoetifolium* 0.2 (sd=0.8). Substrate cover at the West site along 4 transects included live coral 54.6% (sd=36.1), dead coral 6.4% (sd=2.8), coral rubble 15.0(sd=7.0) and sand 25.8% (sd=6.2). An estimated 36% of the live coral was of the genus *Porites. T. crocea* and *T. maxima* were found in habitats with high *Porites* sp. coral cover.

Track Paths

The mean speed obtained from the mobile GPS units was 630m w^{-1} h^{-1} (sd=198, n=24). Based upon a mean search width of 4m, women covered a mean area of 2,520m^2h^{-1} or 0.25ha h^{-1}. When in deeper water, women swam 91% of the time (sd=6%, n=13) and stopped 9% (sd=6%, n=13). When in shallow or exposed reef areas women walked 70% of the time (sd=11%, n=9) and stopped 30% of the time (sd=11%, n=9). Women stopped to either harvest, process, or rest; they swam or walked to either search or reach a harvest area.

Total Biomass and Catch per Unit Effort

The mean CPUE for weight for all invertebrates collected was 2.4 kg $w^{-1}h^{-1}$ and the mean CPUE for weight for all invertebrates per hectare was 6.2 kg $w^{-1}h^{-1}ha^{-1}$. The CPUE in total wet weight for all invertebrates collected (H=10.14) and the CPUE for total wet weight harvested per hour per hectare (H=14) significantly differed between sites ($X^2_{.05[2]}$ value=5.99) as shown in Table 1.

Table 1. Catch per Unit Effort (CPUE) in wet weight (kg $w^{-1}h^{-1}$) and CPUE of wet weight per hectare (kg $w^{-1}h^{-1}ha^{-1}$) for all invertebrates (sd=1) and the number of samples (n).

Site	kg $w^{-1}h^{-1}$	kg $w^{-1}h^{-1}ha^{-1}$
West	2.1 (2.0) n=10	7.3 (13) n=10
South	2.4 (2.2) n=12	6.9 (9.8) n=12
East	2.8 (2.2) n= 6	4.3 (4.9) n= 6
Mean	2.4 (2.0) n=28	6.2 (9.8) n=28

Tridacna crocea and *Tridacna maxima*

The mean clam size for *Tridacna crocea* and *Tridacna maxima* combined for all transects was 7.0cm (sd=3.5, n=208). Women harvested clams ranging from 6.5 to 15cm with a mean size of 10.2cm (sd=1.8, n=130). For all sites, the mean CPUE for the numbers of *T. crocea* and *T. maxima* was 11.8 (sd=11.9, n=37) and the mean CPUE for weight was 0.62kg (sd=0.51, n=32). The CPUE significantly differed between sites for numbers (H=42) and weight (H=204) with an $X^2_{.05[2]}$ value of 5.99 (Table 2). The mean density of clams was 0.07(sd=0.06, n=14) compared to 0.03(sd=0.05, n=78) in 2003. Clam densities, harvest sizes and sizes along the transects showed no significant difference between sites. The percent of clams that were less than the minimum harvestable size (>6.5cm) at each site were as follows: West: 11%, South: 42% and East: 50%.

Table 2. The mean CPUE for counts (ct $w^{-1}h^{-1}$) and weight (kg $w^{-1}h^{-1}$) for *Tridacna crocea* and *Tridacna maxima* (sd=1) and sample number (n). $X^2_{.05[2]}$ value = 5.99.

Site	ct $w^{-1}h^{-1}$	kg $w^{-1}h^{-1}$
West	17.7 (14.4) n=18	0.66 (0.52) n=18
South	5.8 (3.7) n=12	0.26 (0.15) n=10
East	7.1(6.5) n=7	0.15 (0.11) n=4
Mean	11.8 (11.9) n=37	0.62 (0.51) n=32
H	*42	*204

Hippopus hippopus and *Tridacna squamosa*

The mean size for all harvested *H. hippopus* was 22.6cm (sd=6.4, n=43) ranging from 8cm to 45cm. The mean CPUE for numbers of *H. hippopus* was 1.7 (sd=1.45, n=35). The mean CPUE for weight was 1.0kg (sd=0.9, n=26). The mean CPUE for the numbers and the mean CPUE for weight and mean size of harvested *H. hippopus* were significantly different between sites. (The H statistic was 28, 27.6 and 56 respectively; all values were greater than the $X^2_{.05[2]}$ value of 5.99). Mean sizes for each site were as follows: West: 23.3cm (sd=12.7, n=3); South: 22.6cm (sd=6.4, n=43) East: 31.7cm (sd=16.2, n=10). Mean CPUE for counts for each site were as follows: West: 0.83 (sd=0.59, n=6.3); South: 1.81(sd=1.5, n=17) East: 2.16(sd=1.86, n=11). Mean CPUE for weight for each site were as follows: West: 0.76kg (sd=0.79, n=6); South: 0.82kg (sd=0.65, n=11) East: 1.29kg (sd=1.14, n=9). The mean density of *H. hippopus* was 0.011/m^2 (sd=0.007, n=5) compared to 0.002/m^2 (sd=0, n=7) in 2003. The CPUE for *T. squamosa* at the South site was 3.5/w/h.

Tripneustes gratilla

The mean size for all harvested *T. gratilla* was 6.3cm (sd=1.0, n=233) ranging from 4.3 to 11cm. The mean CPUE for the number was 34 (sd=20, n=11). The mean CPUE for weight was 5.6kg (sd=1.3, n=11). The mean CPUE for number and weight significantly differed between the South and West sites (T =18) with a critical value for Rank Sum Test =20 at α=0.05). The East site is not a known site for *T. gratilla*: only dead tests and a few urchins were found. At the South site the mean CPUE for numbers was 47 (sd=13, n=4) during November 2006 and 91 (sd=63, n=3) during March 2007 which was the highest CPUE recorded in this study; the mean CPUE for weight was 4.7kg (sd=1.0, n=5) in November and 18 kg (sd=9.5, n=3) in March; the mean diameter was 6.2cm (sd=0.85, n=95) in November and 6.0 cm (sd=0.54, n=109) in March. During April 15, 2007, *T. gratilla* were observed spawning in the seagrass at 4pm at the South site. At the West site, the mean CPUE for numbers was 27.6 (sd=9.3, n=6), the mean CPUE for weight was 6.4kg (sd=1.1, n=6) and the mean harvest size of 7.6 cm (sd=1.1, n=40) in December 2006. At the East site, 24 empty tests were found along the transect line with a mean diameter of 6.0 cm (sd=0.8, n=24) and a mean density was 0.03/m^2 (sd=0.05, n=3) in June 2007. The mean density for all sites was 0.06/m^2 (sd=0.05, n=3) compared to 0.005/m^2 (sd=0.004, n=10) in 2003.

Actinopyga sp.

The mean CPUE for numbers of *Actinopyga* sp. was 25 (sd=25, n=12) and the mean CPUE for weight was 2.8kg (sd=2.8, n=17). The mean size was 11.1cm (sd=3.5, n=124). This species was not found at the South site. The West and East sites significantly differed for mean CPUE for numbers and weight. At the West site, the mean CPUE for counts was 8.2 (sd=16.6, n=6) compared to 38.5 (sd=24.7, n=6) at the East site. The mean CPUE for weight was 0.53kg (sd =0.7, n=6) at the West site and 3.2kg (sd=3.0, n=14) at the East site. The mean size was 9.8cm (sd=2.3, n=28) at the West site and 11.5cm (sd =3.8, n=96) at the East site. The mean density was 0.003

(sd=.006, n=6) at the West site and 0.10 (sd=.006, n=6) at the East site. The mean density for both sites was 0.05/m^2 (sd = 0.11, n=12) and lower than the mean density of 0.07/m^2 in 2003.

Stichopus vastus

For all sites, the mean CPUE for numbers was 22.4 (sd=23.8, n=40) and the mean CPUE for weight was 3.2kg (sd=3.8, n=18). The mean CPUE for numbers, significantly differed (H=41) between sites as follows:West:30.2 (sd=25.7, n=29); South: 4.8 (sd=16.9, n=6); and East:11.9(sd=6.1, n=5). The mean CPUE for weight significantly differed (H=19) between sites as follows: West:3.8kg (sd=4.3,n=12); South:2.0kg (sd=3.0, n=3): East:1.2kg(sd=0.6, n=3). Densities significantly differed (H=31) between sites as follows: West: 0.05(sd=0.07, n=6); South: 0.92 (sd=0.86, n=6); and East: 0.009(sd=0.008, n=6). The more accessible areas of the West site had lower mean CPUE for numbers 1.0 (sd= 0.9, n=3) and weight 0.2kg (sd=0.09, n=3) than less accessible areas with a mean CPUE for counts of 19.9 (sd= 18, n=8) and a mean CPUE for weight of 7.0kg (sd=4.6, n=6). Higher mean densities of *S. vastus* were also found at the South site in the 2003 survey (Table 3). The mean size for all harvested *S. vastus* was 17.9cm (5.0, n=17) compared to 14.7cm (sd=2.3, n=1,388) in 2003.

Table 3 *Stichopus vastus* density (ct/m^2) with the standard error (SE) and sample number (n)

	2006-2008(ct/m^2)	2003 (ct/m^2)
West	0.01(0.01) n=2	0.05(0.07) n=6
South	0.94 (0.93) n=3	0.80(0 .76) n=3
East	0.01(0.003) n=2	0.02(0.003) n=2)
Mean	0.41(0.73) n=7	0.24(0.48) n=11

Holothuria scabra

For all sites, the mean CPUE for numbers of *H. scabra* was 6.7 (sd=5.8, n=10) and the mean CPUE for weight was 1.3kg (sd=1.2, n=10). The CPUE for numbers (H=16) and weight (H=15.7) significantly differed (the Kruskal-Wallis critical value$_{.05[2]}$= 5.25) between sites. The mean CPUE for numbers at each site was as follows: West: 10.7 (sd=4.7, n=5); South: 5.0 (sd=5.7, n=2); and East: 1.1 (sd=0.6, n=3). The mean CPUE for weight at each site was as follows: West: 2.1kg (sd=0.9, n=5); South: 1.2kg (sd=1.4, n=2); East: 0.2kg (sd=0.1, n=3). The mean density for all sites was 0.009/m^2 (sd=0.009, n=8) compared to 0.005/m^2 (sd=0.008, n=12) in 2003. The mean length was 14.5cm (sd=2.4, n=29) compared to 14.9cm (sd=13, n=6) in 2003 and 16.8cm (SE=0.6, n=17) for the 2007 SPC survey.

Lambis lambis

Lambis lambis had a mean size of 12.4cm (sd=2.3, n=13) and a mean weight of 0.3kg. The mean CPUE was 0.8 (sd=1.2, n=22). The CPUE for counts significantly differed (H=10, $X^2_{.05[2]}$ value=5.99), between sites as follows: South: 1.4 (sd=0.9, n=8); East: 1.2 (sd=0.7, n=4); and West: 0.6 (sd=0.3, n=4). The mean density of 0.004/m^2 (sd=0.003, n=3) was similar to the mean density of 0.005/m^2 (sd=0.004, n=10) in 2003. The mean size was similar to the 2007 PROCFish study by SPC.

Market Value

The mean purchase price for several invertebrate species between 2000 and 2007 was $6.00/kg at a local market. The mean annual sales were as follows: *Actinopyga* sp.: 1098kg, *T. crocea* and *T. maxima*: 148kg and *S. vastus*: 99kg. The retail values in 2008 were as follows: *T.crocea* and *T. maxima* meat: $10kg^{-1}, *S.vastus*: $10.80kg^{-1}; *H. scabra*: $10.50kg^{-1}; *T. gratilla*: $11kg^{-1}; sliced *Actinopyga* sp.: $6.50kg^{-1} and minced: $4kg^{-1}. The time required to harvest 1kg of these species based upon the mean CPUE for weight (not including transport and processing time) is as follows: *T.crocea* and *T. maxima* meat: 1.6h, *S.vastus*: 0.33h; *H. scabra*: 0.75h; *T.gratilla*: 0.18h and *Actinopyga* sp.: 0.3h. Revenues generated from hourly harvest ranged from $13 for *Actinopyga* sp. to $61 for *T. gratilla*. Commercial production showed an increasing trend for Yano's market (Evelyn Yano, unpublished data, 2008). Increased local demand for these delicacies by residents and visitors puts pressure on this fishery and some are illegally exported. Currently there are no national regulations for *S.vastus* or *T. gratilla.*

Discussion

The harvest rates of selected invertebrates showed high percent declines compared to a qualitative survey 17 years ago (Matthews and Oiterong 1991). The percent declines in harvest rates compared between 2007 and 1991 were as follows: embedded *Tridacna* species (60%), *H. hippopus* and other *Tridacna* species (75%), *S. vastus* (50%) and *H. scabra* (80%). The Belau Mariculture Demonstration Center (BMDC) produces clams that reach maturity within 5 years and have recommended minimum sizes to harvest wild clams. The size at first maturity of cultured clams and the recommended harvest sizes for wild clam populations in Palau are as follows: *T. crocea* (8cm; 12cm), *T. maxima* (10cm; 12cm), *H. hippopus* (12cm; 18cm), *T. squamosa* (18cm; 18cm) and *T. derasa* (30cm; 35cm) (Lawrence Sumer-BMDC supervisor, pers comm. 2008). Jameson (1976) observed *T. maxima* spawning at sizes ranging from 11cm to 13cm. The mean size of harvested *T.*

crocea and *T. maxima* in this study were lower than the recommended harvest size. The mean harvested size for *H. hippopus* was within BMDC's recommended size range and similar to the mean size in the 2007 SPC study. *Tridacna crocea* and *T. maxima* clams are good indicator species of reef health for *Porites* spp. dominated reefs because they are common and accessible, have a colorful mantle, and leave a depression after extraction, enabling easy detection and measurement. *Hippopus hippopus* is a potential early indicator species of overharvesting because women prefer it because it is easier to harvest and has larger meat than the embedded clams. However it is found in lower densities. Women transplanted smaller *H. hippopus* to depleted areas.

In the Philippines, densities of *T. gratilla* dropped from 0.11-2.14/m^2 to 0.02 to 0.07/m^2 prior to the collapse of the urchin fishery in 1992 (Juninio-Meñez et al. 1998). In this study, the mean density was 0.06/m^2 and 0.005/m^2 in 2003, which were similar to the threshold densities in the Philippines prior to its collapse. The mean diameter of harvested *T. gratilla* was similar to sexually mature cultured *T. gratilla* (6cm) in the Philippines and wild populations in other regions (Juinio-Meñez et al. 1998). In Palau, sea urchins were more abundant from November 2006 to March 2007 and were observed spawning in synchrony during April 2007. Breeding peaks were between September and November in the Philippines and Taiwan, (Chang-Po and Ku Hsiung 1981). Algal food availability (Conan and Sloan 1989) and macroalgae preferences (Stimson et al. 2007) were correlated to *T. gratilla* abundance and distribution. Temperature and photoperiod changes acted as cues to induce spawning in *T. gratilla* (Vaïtilingon et al. 2005). Coral (Penland et al. 2004), plants (Borchert 2005, Kitalong 2008), *Acanthaster plancii* (Idip 2003) and *Siganus fuscescens* (Kitalong et al. in prep) exhibited reproductive peaks that correlated with annual spring and fall maxima in solar insolation. Fisherfolk have observed that *T. gratilla* become buoyant and move in masses from reef to reef. They believe that urchins live in deep water and emerge to the shallows to breed. We found only empty tests in June at the East Site. During extensive surveys during May 2007 and the summer of 2003, only 4 and 3 urchins were found respectively (SPC 2007, Kitalong 2003), suggesting seasonality for this species in Palau.

Actinopyga sp. used coral as a refuge during daylight and emerged at night at the West site. *Actinopyga* sp. harvest rates were similar to estimated rates 17 years ago (Matthew and Oiterong, 1991). The mean size of harvested *Actinopyga* sp. in this study was 11cm which was smaller than the size of mature *Actinopyga echinites* (12cm) found by Conand (1982). In this study, *Actinopyga* sp. were common at the East site however women limited their harvest effort for *Actinopyga* sp. because it required several hours to process its edible endodermis. Women preferred to collect *H. hippopus*, *T. gratilla* and *H. scabra* which were easier to process.

The mean size of *S. vastus* decreased from west to east in this study and in 2003. Women said they preferred harvesting *S. vastus* at the West site because it "tasted better" than at the other sites. Their preference is reflected in the high CPUE rates yet lower densities at the West site compared to the South site. The author and fishers have observed a decline in populations at accessible sites. Women traditionally slice *S. vastus* into 2 or 3 sections and scatter them onto the depleted areas. *Stichopus vastus*(?) spawned during April 2003 at a southern reef.

The mean size of harvested *H. scabra* in this study compared to other countries indicates that they have not reached sexual maturity. *H. scabra* are known to emerge from the sediments on incoming tides at dusk. Juveniles burrow during sunrise and emerge during sunset to feed (Mercier et al. 1999). We observed similar behaviour in this study. The decline in *H. scabra* has been attributed to overharvesting and pollution from land based sediments and other pollutants. Golbuu et al. (2003) found high rates of sedimentation in Airai Bay.

Small patchy populations require measurement at fine spatial and temporal scales with input from resource users to better estimate and detect population change. Fishers are observing more restricted habitats and smaller sizes for most invertebrates. Mobile GPS tracking units locate specific habitats for targeted species for future monitoring. Experienced gleaners showed the less experienced gleaners the proper harvest sizes and how to harvest embedded clams without damaging corals. Sustainable harvesting skills must be taught in the field. Teamwork between managers and fishers enhanced implementation of this study and the exchange of valued information which provided more management options. These results can be used to educate the community; set size limits, threshold densities, seasonal harvest periods and site closures of important pre-spawning and spawning grounds. These key invertebrates can serve as potential indicators of reef health. Their functional roles as grazers, aerators of sediment and processors of organic matter are essential in maintaining a healthy reef.

During village meetings, the community recommended the following actions: stop dredging the inner reef areas, protect important areas for each

village, restrict boat traffic, reduce or stop sources of pollution, conduct more studies, develop sustainably, involve communities in activities and employ more conservation officers. Currently protected areas are being demarcated and Airai conservation officers are monitoring and enforcing marine laws with their local research, enforcement and community partners.

Acknowledgement

National Oceanic Atmospheric Administration Coral Reef Conservation Program funded this project and especially Andy Bruckner and Liz Fairey who were very supportive. The Palau Automated Land and Resource Information System (PALARIS), the Bureau of Marine Resources, the Palau Conservation Society, the Palau International Coral Reef Center, the Coral Reef Research Foundation, and the Division of Fish and Wildlife Protection were committed partners throughout this investigation. This study would not have been possible without the active participation of the women of Ngarabrekork and their families: Nancy Mengloi, Ngemelas Kitalong, Dengir Masami, Rosania Mad, Rachel Dulei, Kerungil Misech Marcellino, Teresa Ililau, Josephine Ngirarikel, Gemma Ngirchobong, Tina Rehuher, Marygold Yobech, Rose Telmang, Auleliang Alfonso, Rikel Alfonso, Margaret Sei-ichi, Laine Rubeiang, Joanne Yobech, Omekatel Baliyok, Skalsol Ngirdimau, Lea Takeo, Linda Tomei, Esichang Ngirmekur, Josepha Tomei and Siabal Ililau. The Ngarameliwei secretary Obak Clarence Kitalong, McKnight McArthur and Christopher Ongrung were invaluable participants. The women and men shared their knowledge, skills and time with great enthusiasm. Governor Vicky Kanai, the Airai State Staff, the Airai State Legislators, the Airai State Planning Commission, the Airai State conservation officers and the community as a whole continue to support our efforts. Kmal mesulang!

Abstract. Palmyra Atoll National Wildlife Refuge is the second largest atoll under U.S. jurisdiction in the Pacific Ocean. Until recently, little was known about benthic communities and, more specifically, algal abundance at Palmyra aside from species lists generated during 1916, 1955 and 1959 expeditions. Since 2000, NOAA's Pacific Islands Fisheries Science Center, Coral Reef Ecosystem Division has conducted six rapid ecological assessment surveys to monitor and gather baseline data for reefs surrounding Palmyra. Additionally, Scripps Institute of Oceanography documented benthic community structure on Palmyra's reefs during a 2005 expedition. This study reports on the current state of knowledge for benthic community composition and algal community structure across the atoll. Benthic communities in fore reef areas (10 m depth) were dominated by reef builders (coral and crustose coralline algae) covering ~50% of the benthos, while turf algae, macroalgae, soft corals, and other invertebrates covered the remaining surfaces. Species of *Halimeda*, *Lobophora*, *Dictyosphaeria*, *Galaxaura* and *Dichotomaria* were among the 5 most common macroalgae recorded. Overall, the reef communities around Palmyra appear relatively healthy. Developing comprehensive species lists and continuing benthic monitoring will allow reef managers to detect ecosystem changes, including possible introduced and invasive species.

Key words: algae, benthic community, coral, monitoring

Introduction

Palmyra Atoll, located in the northern portion of the Line Island Archipelago, is situated 1692 kilometers southwest of the Hawaiian Islands in the intertropical convergence zone (Maragos et al. 2008, Miller et al. 2008). It is the second largest of 10 atolls under US jurisdiction, and is composed of 182 and 6,277 hectares of emergent and submerged habitat, respectively (Handler et al. 2007; Rohmann et al. 2005). Although composed of several vegetated islets, Palmyra Atoll's geographically remote location has never fostered permanent human population. Thus, the atoll remained in near pristine condition until the early 1940s when it was turned into an US military airbase during World War II. An airstrip was constructed by dredging the central lagoon and using the debris to connect existing islets. A large ship channel was also dredged to allow military vessels to enter the calm lagoonal waters.

In 2000, Palmyra's largest island (Cooper Island) was purchased by the Nature Conservancy and a research station was built (Miller et al. 2008). In 2001, all remaining areas of Palmyra Atoll (excluding Cooper Island) were purchased by the US Fish and Wildlife Service and were designated a National Wildlife Refuge, thus increasing Palmyra's protected status (Miller et al. 2008). A recent study investigating the fish and benthic communities of the northern Line Islands found that the reefs of Palmyra and the more northerly Kingman Reef were characterized by high apex predator biomass in similar proportions to those found in the uninhabited Northwestern Hawaiian Islands (Sandin et al. 2008; Stevenson et al. 2007). Therefore, in spite of previous environmental changes made by the US military, 60 years devoid of human disturbance and Palmyra Atoll's distance from large human populations have allowed marine communities around the outside of the atoll to remain in a reasonably pristine state (Brainard et al. 2005; Sandin et al. 2008), offering a relatively unperturbed marine system for study.

Despite several early species lists (Rock 1916, Dawson et al. 1955, Dawson 1959), little has been reported about algal communities surrounding Palmyra Atoll. New species of marine algae from Palmyra were reported through the 1960s (Hollenberg

1968) and recent coral community monitoring has been performed (Williams et al. 2008; Maragos et al. 2008; Miller et al. 2008). However, no comprehensive analysis of algal community composition has yet occurred.

The goals of this study were to use two of the most comprehensive data sets available on benthic community composition of Palmyra's reefs to examine spatial patterns in functional group abundance, and more specifically, macroalgal abundance around the atoll. NOAA's Pacific Islands Fisheries Science Center (PIFSC), Coral Reef Ecosystem Division (CRED) has been examining benthic community biodiversity and abundance on reefs surrounding the atoll in 2000 and 2001 and biennially from 2002 to 2008. Additionally, in 2005, a comprehensive study of Palmyra reef communities was conducted by Scripps Institute of Oceanography (SIO; Sandin et al. 2008). Using these two complementary data sets, benthic communities were examined to (1) understand spatial patterns in percent cover of benthic functional groups, and (2) increase knowledge of macroalgal community composition. These results will be used as a baseline for future monitoring of Line Islands reefs, providing valuable insight for management efforts investigating the role played by algal communities at Palmyra Atoll (National Marine Fisheries Service, 2006).

Table 1: CRED and SIO (indicated with a B) benthic survey sites at Palmyra Atoll.

Materials and methods

Field Location

Palmyra Atoll (Figs 1, 2, Table 1) is one of 11 atolls and low islands situated in the Line Island chain, and sits atop a shallow bank <100 m below sea level. Large shallow (<30m) reef terraces extend from the eastern and western shores, with northern and southern shores exhibiting relatively narrow strips of fore reef area that rapidly drop to abysmal depths (National Marine Fisheries Service 2006; Maragos et al. 2008; Miller et al. 2008). Survey sites occurred between 3m to 15m depths in both reef terrace and fore reef habitats (Figs. 1, 2, Table 1). No survey sites were located within lagoonal habitats, although survey sites PAL-04 and PAL-16P were located adjacent to a dredged channel leading to the SW corner of the lagoon (Table 1, Figs. 1, 2).

Benthic Surveys

Quantitative Rapid Ecological Assessment (REA) surveys were conducted across the atoll by two research organizations: (1) NOAA's CRED established 20 sites between 2000 and 2008, and (2) SIO conducted an expedition in 2005 that surveyed 10 sites. CRED sites were stratified across reef terrace and fore reef habitats at ~15m depths (when possible) (Table 1) and subsequent surveys emphasized previously surveyed sites. SIO sites were all located in fore reef habitats at 10m depths and were located at 2km intervals around the atoll (Table 1). At each site, 2 transect lines of either 25m (CRED) or 50m (SIO) were deployed and 12 – 20 photographs were taken using a photoquadrat (CRED = 0.18m^2, SIO = 0.54m^2) equipped with a digital still camera (Preskitt et al. 2004) along each line for a total area surveyed of 2 – 10m^2 per site. Photographs serve as permanent documentation of each site and were analyzed for benthic percent cover using the Coral Point Count with Microsoft Excel extensions (CRED; CPCe; Kohler and Gill 2006) or PhotoGrid (SIO) software to assign one hundred stratified random points to each digital image.

Benthic percent cover data were divided into the functional groups of coral, crustose coralline red algae (CCA), turf, and macroalgae. Macroalgal data were further identified to the lowest taxonomic level possible. To examine whether community composition (functional group abundance) was similar across habitats within each sampling year, one-way analyses of similarity were performed (ANOSIM; number of permutations = 5,000) using Bray-Curtis Similarity Indices (based on fourth root transformed abundance data) performed in PRIMER-

E v.6. Data between sampling years were not combined in spatial analyses. SIMPER analyses were performed to determine which functional groups and/or algal species were contributing the most to differences or similarities between sites.

Results

Benthic Community Composition

Benthic communities surrounding Palmyra Atoll were relatively homogeneous in terms of functional group abundance (Table 2). ANOSIM results examining benthic community composition between fore reef and terrace habitats found no differences within each sampling year (Global R (p-value): 2004 = 0.071 (0.003), 2006 = 0.15 (0.018), 2008 = 0.131 (0.0002)). Similarly, no differences were observed among sites (regardless of habitat) in 2004, 2005 or 2006 (Global R (p-value): 2004 = 0.214 (0.0002), 2005 = 0.174 (0.0002), 2006 = 0.098 (0.0002)); although ANOSIM site comparisons revealed differences in 2008 (Global R (p-value) = 0.351 (0.0002)). From 2004 through 2008, percent cover of macroalgae ranged from 3 to 58% (Fig. 1) (average = 19%), reef builders (coral and crustose coralline red algae) ranged from 10% to 71% (average = 45%), and turf algal cover ranged from 7% to 70% (average = 30%).

In 2008, individual pairwise *r*-values from the ANOSIM test revealed that the difference observed in Global R values stemmed from differences in benthic community composition between western terrace sites (PAL-02, PAL-04, PAL-05,and PAL-06) and the rest of the atoll (Figs 1, 2). SIMPER revealed *Halimeda opuntia* to exhibit a percent cover of 32% at PAL-02, accounting for 17 – 31% of observed dissimilarities between this site and all others (PAL-02 pairwise *r*-value range = 0.022 – 0.824, median = 0.279). PAL-04, located on the western reef terrace near the boat channel, contained a dense community of the red macroalga *Dichotomaria marginata* that covered 37% of the substrate. The alga was not observed elsewhere around the atoll, therefore driving statistical differences between PAL-04 and other sites (pairwise *r*-value range = 0.01 – 0.853, median = 0.333). SIMPER analysis revealed that *D. marginata* accounted for 21 – 59% of the dissimilarity between PAL-04 and all other sites. Similarly, PAL-05, located on the NE fore reef, was different from 6 of the 8 sites surveyed in 2008 (*r*-value range = 0.204-0.853, median = 0.638). At PAL-05, turf algae covered 70% of the substrate and accounted for 34 – 39% of the dissimilarity found between this and other sites. A corallimorph that covered 69% of the substrate at PAL-06 (and was not seen elsewhere around the atoll) contributed to 38 – 43% of dissimilarities observed (PAL-06 *r*-value range = 0.553 – 0.664, median = 0.633).

Table 2: Average percent cover of benthic functional groups from survey sites from 2004-2008. Average percent cover of photoquads for each site during each year are presented. Standard errors not shown because of space limitations. CCA = Crustose Coralline Red Algae.

In 2004, percent cover of live coral at site PAL-16P was only 4% (compared to an average of 37% around the rest of the atoll), and this functional group contributed to 13 – 47% dissimilarity between PAL-16P and other sites during this sampling year (PAL-16P *r*-value range = 0.257 – 0.734, median = 0.42). PAL-16P site has not been resurveyed since.

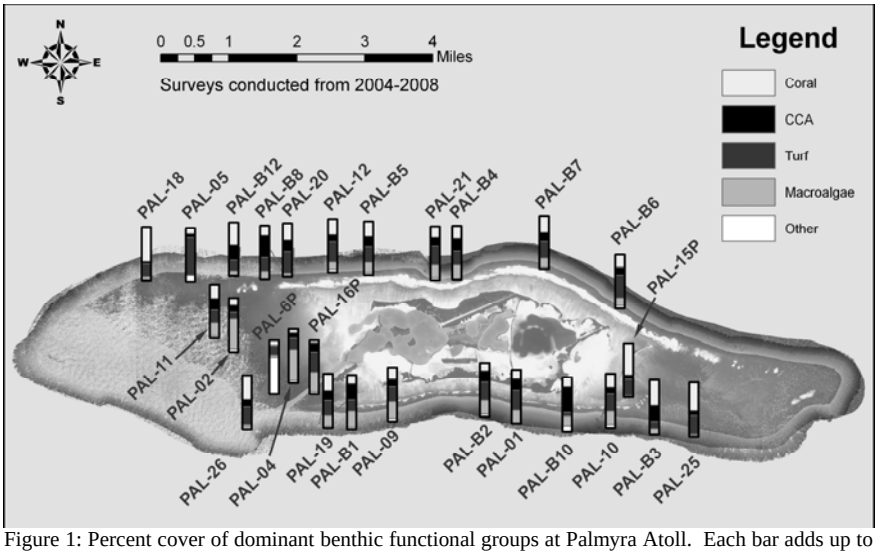

Figure 1: Percent cover of dominant benthic functional groups at Palmyra Atoll. Each bar adds up to 100% cover. Percent cover data from sites visited in multiple years were averaged (Table 2).

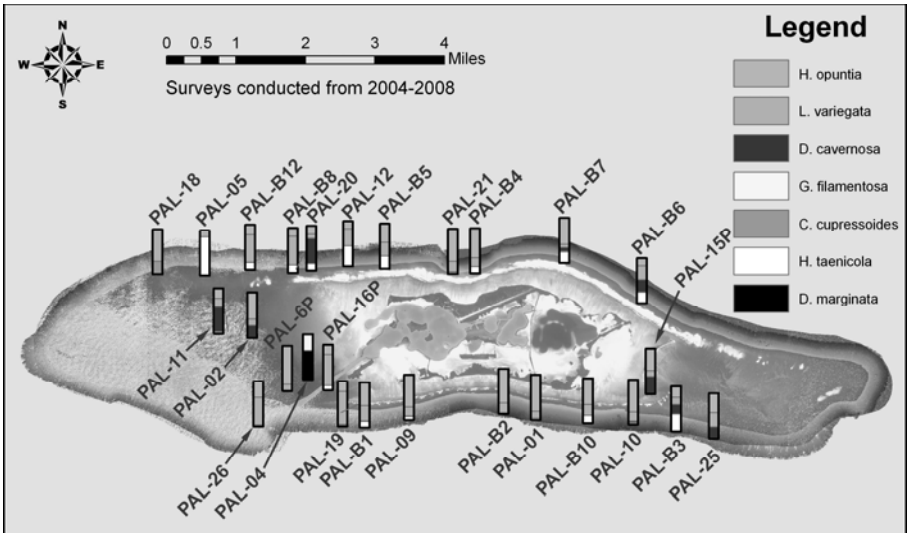

Figure 2: Relative abundance of select macroalgal species at Palmyra Atoll. Each bar shows percent contribution of each algal species to total macroalgal cover present at each site. Percent cover data from sites visited in multiple years were averaged (Table 2).

Algal Community Composition

Nineteen species of macroalgae were documented in photoquadrats at Palmyra Atoll. Of these, *Halimeda opuntia* was the most common, exhibiting a percent cover range of 0 – 46% (average = 8.2%). *Lobophora variegata* (percent cover = 0 - 27.7%, average = 5.3%), *Galaxaura filamentosa* (percent cover = 0 – 37%, average = 1) and *Dictyosphaeria cavernosa* (percent cover = 0 – 16.5%, average = 1.6%) were the next most common species.

ANOSIM analyses performed on macroalgal percent cover data (omitting all other functional groups) found algal communities to be relatively similar across the atoll (Global R: 2004 = 0.196; 2005 = 0.073; 2006 = 0.48; 2008 = 0.184, significance = 0.02%); however, PAL-04 (Fig. 2) showed a statistically significant difference in macroalgal percent cover from 5 of the 8 other sites surveyed in 2008 (*r*-value range = 0.623 – 0.997, significance.

Discussion

Overall, the outer fore reef areas of Palmyra Atoll remain healthy, presumably because of the lack of current anthropogenic influences. Benthic community structure is dominated by reef building organisms, primarily coral and CCA at 82% of sites. At only four sites did macroalgal cover exceed that of either reef builders or turf algae, a finding similar to that of a previous study at eight other relatively pristine Pacific reefs, where macroalgal cover was lower than that of coral at 67% of sites (Vroom et al. 2006). Findings at

Palmyra are also in line with those from Kingman Atoll, the closest island to Palmyra, where benthic cover was dominated by reef-building organisms in contrast to macroalgal dominated substrates around the more densely populated islands of Tabuaeran and Kiritimati (Sandin et al. 2008).

The high percent cover of the red alga *Dichotomaria marginata* and a corallomorph documented at PAL-04 and PAL-06, respectively, may be due to these site's close proximity (477m) to a 37m, steel-hulled, long line vessel which ran aground in 1991. Changes in algal communities have also been observed to occur in close proximity to a 1993 shipwreck on Rose Atoll (Schroeder et al. 2008). Rose Atoll was monitored by CRED from 2002 to 2006 and exhibits percent cover of opportunistic algal species two times higher at the shipwreck site as compared to sites further away. Additionally, Work et al. (2008) found high densities of the corallimorph, *Rhodactis howesii*, to occur within 1 km^2 of the Palmyra wreck suggesting possible correlations with nutrient availability and changes in benthic communities. Further research examining nutrient levels at PAL-04 and PAL-06 are needed to definitively link the shipwreck at Palmyra Atoll with increased percent cover of *D. marginata* and corallomorphs.

Finally, the protected status of Palmyra Atoll guarantees that the surrounding reef communities will be spared from any direct human impacts, allowing Palmyra Atoll and other remote reefs to serve as important natural laboratories for understanding the impacts of climate change on coral reefs.

Acknowledgements

Thanks to the crews of the NOAA ships *Townsend Cromwell, Oscar Elton Sette* and *Hi`ialakai* for field support. Thanks to K Page-Albins, L Preskitt, A Tribollet, B DeJoseph, R Moffitt for assistance with collection of algal and benthic data. Funding to CRED for the Pacific Reef Assessment and Monitoring Program to the U.S. Pacific Remote Island Areas provided by the NOAA Coral Reef Conservation Program is much appreciated. We also thank the crew of the *ORV-White Holly* and the members of the SIO Line Islands Research Expedition namely S. Sandin for organizing and coordinating all field work.

Assessment of Resilience in *Montastrea faveolata* Inside and Outside of a Marine Park

E.M. Mueller[1] and C. J. Booker[2]
[1] Perry Institute for Marine Science, Jupiter, FL
[2] College of Charleston, Charleston, SC

Abstract

Lesion regeneration (wound healing) was used as a proxy for assessing organismal resilience in the coral, *Montastrea faveolata*. Potential effects of wounding on quantum yield determined by PAM fluorometry were also examined. In a mesocosm experiment, surface lesions were imaged daily over 15 days to develop healing curves. Quantum yields were obtained daily using a PAM fluorometer (2 mm fiberoptic). Results demonstrated that 50% healing occurred in 5-6 days. Lesion healing was compared between an unprotected location near Lee Stocking Island (Exuma, Bahamas) and in the Exuma Cays Land and Sea Park using coral cores deployed to field arrays at each site. Lesions, images and PAM measurements were made on day 0 and again 5-7 days later. These procedures were repeated in the winter, spring and summer of 2007 and winter, 2008. There were no seasonal differences in healing rates or between genotypes. No consistent effects of site, time of year or wounding were seen on quantum yields of surrounding tissue, however, newly formed tissues had significantly lower yields than measured in undamaged tissues. Healing was significantly greater at the Park site in the winter of 2007 but there were no site differences in spring or summer.

Key words: corals, organismal resilience, coral stress, wound healing

---

Introduction

There is a broad consensus that reef corals are threatened by a variety of anthropogenic and natural stressors. This has increased interest in assessing organismal stress and resilience. Some approaches, such as measuring coral growth, are inexpensive and simple but usually take considerable time for results to be obtained. Other methods are more rapid and can also provide very specific information. These include measurement of photosynthetic performance and/or competence, determination of calcification rates and a broadening array of cellular biomarkers. Drawbacks include higer costs, technical expertise requirements or access to a suitable laboratory.

Several investigators have examined lesion regeneration (wound healing) in response to environmental conditions such as turbidity and sedimentation (Lester and Bak 1985; Meesters et al. 1992; Cróquer et al. 2002), bleaching (Meesters and Bak 1993; Mascarelli and Bunkley-Williams 1999; Fine et al. 2002) or pollution (Williams 1994). Results from these and other studies (Bak et al. 1977; Meesters et al. 1994; 1997; Nagelkerken et al. 1999; Oren et al. 2001) suggest that wound healing reflects overall physiological condition and response to the environment. These findings led to proposals (Meesters and Bak 1994; Williams 1994) and projects (Fisher et al, 2007) to use lesion regeneration as a measure of coral condition.

In addition to environmental conditions and species (Bak and Van Es 1980; Nagelkerken and Bak 1998; van Woesik 1998; Nagelkerken et al. 1999), results from previous studies have demonstrated that lesion size and shape have a profound effect on healing rates (Meesters et al. 1994, 1997; Oren et al, 1997; Loya 1997; van Woesik 1998; Lirman 2000; Hall 2001). Large lesions heal more slowly, are more susceptible to enlargement by grazers (Cróquer et al. 2002) or colonization by epibionts (van Woesik 1998; Hall 2001), in some cases preventing complete closure (Mascarelli and Bunkley-Williams 1999; Cróquer et al. 2002) or allowing establishment of disease such as black-band (Cróquer et al. 2002).

To be useful for comparing coral resilience over time and space, the lesion regeneration method should minimize impact on corals and be standardized with respect to species, colony size and environment, lesion characteristics and measurement. Here we present and propose a Coral Resilience Assay that meets these requirements and is rapid, inexpensive and requires little technical expertise. The method is applied to examine whether corals in the Exuma Cays Land and Sea Park, a well-established marine protected area, have greater resilience than in unprotected areas.

Methods

Mesocosm Experiment

Four 1" diameter cores were extracted from each of four *Montastrea faveolata* colonies using a carbide core bit. Colonies had been maintained in a 16,000-liter tank 23-28 months, thus all had been exposed to similar environmental conditions. The mesocosm experiment described here was also conducted within this tank. Cores were mounted to 2" square plastic PVC or ABS plates using epoxy (Quick Fix 2300; Progressive Epoxy Polymers, Inc.) and allowed to recover for several days.

Digital plan images of each core were recorded (Nikon 3100; 2048x1536 pixels) with a 1-cm scale and pulsed-amplitude modulated fluorometry (Walz Diving PAM) measurements performed. These tasks were accomplished using the COral Resilience Assessment System (CORAS; see Mueller 2008 for details and images). The CORAS is a submersible platform that allows repeatable positioning of the cores in three axes (X-Y-Z). Using a 2-mm optic fiber, two PAM measurements were made at each of the four cardinal points (N, E, S & W). The first was 3 mm from the area to be wounded (see below) and the second 5 mm distal to the first. Angle of the fiber optic was 45 and it was held 3 mm above the coral surface. Procedures were conducted at mid-day and corals were not dark adapted, thus, yield measurements are apparent.

On 9/24/06, a 5/16" carbide end mill was used to make a ~0.5 cm^2 wound in the center of three cores from each colony to a depth of 2-3 mm; the fourth core was left as a control. All cores were re-imaged and PAM measurements made immediately following wounding. All were imaged daily until 10/10/06, 16 days after wounding. Wound areas in each image were calculated using SigmaScan Pro (V.5).The PAM measurements described above were conducted daily 9/24-28/06 then on 9/30/06 and 10/2/06. On 10/9/06, PAM measurements were made in just two locations on each coral, on a portion of healed lesion and on tissue that had not been injured. Temperature and conductivity (salinity) were recorded at 10 min. intervals (Alec Electronics).

Site Comparison with Cultured Corals

Twelve 1" cores were removed from six cultured *M. faveolata* colonies (different from those in the previous experiment), mounted on PVC plates and secured to six PVC field arrays (Fig. 1). The six colonies were each represented by two cores on each array; the exact cores and their positions within each array were randomly selected. Three arrays were installed Jan., 2007 at Jeep Reef (EX01) in the Exuma Cays Land and Sea Park (ECLSP; a no-take area) and three at North Norman's Reef (EX02) near Lee Stocking Island (unprotected). Both sites were on sand near patch reefs with similar depths (6-7 m). One array at each site was instrumented with a conductivity-temperature logger and a depth recorder (Alec Electronics).

Over the following year, coral responses to wounding were seasonally examined (winter 2007, spring 2007, summer 2007 and winter 2008). Coral cores were retrieved from the arrays and brought to a shore-side seawater system overnight. They were imaged and PAM measurements conducted. After wounding, these procedures were repeated and the cores returned to the field arrays for 5-7 days. They were again retrieved for imaging and PAM measurements. Procedures were similar to that described above with the following differences: images were made with a higher resolution camera (Sea & Sea DX8000; 3264x2448 pixels), four (rather than 8) PAM measurements were made per core at each of the cardinal points and wounds were made with a 5/16" stainless steel rod. Instruments were serviced and downloaded during each assessment period.

Site Comparison with In Situ Corals

Wound healing assessments were conducted in February and March/April 2008 near Warderick Wells (WW) in the ECLSP and in Elizabeth Harbour (EH) near George Town, the largest population center in the Exumas (Feb. April, and May, 2008). Within both study areas, four mature *M. faveolata* colonies of similar size and condition were haphazardly selected at each of four similar patch reefs (16 colonies within each study area). Four wounds per colony (at least 10 cm apart) were made on the colony top surface with a 5/16" punch. Wounds were imaged (Canon SD800; 3072x2304 pixels) with a 1-cm scale and repeated 5 days later. Wound areas were assessed using Coral Point Count with Excel Extensions V 3.5 (Kohler and Gill 2006).

Results

Mesocosm Experiment

The end mill wounds were somewhat ragged, thus, the day after the wounding (9/25/06), when tissue had sloughed off, was used as the basis for initial lesion size. Thus, the number of days shown on the graphs is 15 rather 16 days. Fig. 1 shows an example of the healing observed the experiment. The first wounds healed 100% by day 13 and by the end of the experiment (day 15), five of the 12 wounds had completely healed. Three months later (data not shown), all but two cores had completely healed.

The healing of the three replicate cores was averaged to represent each colony and the four colonies averaged to produce grand means for each day. The recovery curve for all cores over the initial 15 days is shown in Fig. 2. The 50% lesion recovery time was just over 5 days.

No effects of wounding were observed on the apparent quantum yields of tissues proximal (~3 mm) or distal (~8 mm) to the lesion. However, newly healed tissues had significantly lower apparent quantum yields than the adjacent undamaged tissues.

Site Comparison with Cultured Corals

Over the 1-year of this experiment, tissue loss resulted in morbidity that precluded making all four PAM measurements or complete mortality of the coral core. Based on the initial 72 cores, the morbidity rate over the year was 35% and the mortality 14%. Corals fared most poorly during the period (8/07-1/08) prior to the last assessment. Factors responsible could include maximal temperatures of 31-32º C at both sites (8/07) and Tropical Storm Noel (11/07) that produced salinities as low as 30 ppt (EX02; 34 ppt at EX01).

Normalized healing (% of initial lesion day^{-1}) at all sites in all seasons are compared in Fig. 3. Because no field measurements were made in the Fall, the mesocosm experiment results ("LSI") are shown for comparison. With the exception of healing at EX02 in the Winter of 2007, averaged healing at all locations throughout the year was typically 9-11 % day^{-1}. The only significant site difference was in Winter, 2007 where wounds at EX01 healed faster than at EX02.

Overall, there were no seasonal effects. ANOVA results indicate that there were no genotypic differences. Apparent quantum yield (F_v/F_m) values typically ranged from 0.4-0.6 under subdued mid-day lighting. No significant differences were attributable to sites, season or genotype.

Site Comparison with In Situ Corals

Regeneration of lesions on *M. faveolata* colonies in situ were generally similar to those seen on the 1" cores in the previous experiments. During the February 2008 assessment, coral lesions at the Warderick Wells sites healed significantly faster than those in Elizabeth Harbour (Fig. 4). The mean healing rate for all colonies (n=16) at the four WW sites was 11.74±3.09 % day^{-1} and for the EH sites 7.63±3.72 % day^{-1}. A repeat of the procedures in March/April on the same colonies did not show a significant difference between the study areas (WW: 8.51±3.78 % day^{-1}; EH: 7.28±3.30 % day^{-1}). The regeneration rates at the WW sites were lower during the second assessment but not significantly so.

Discussion

The Coral Resilience Assay has been applied to corals in several experimental settings: cores derived from cultured parents in mesocosm- and field-based experiments and colonies *in situ* on patch reefs. The Assay resulted in consistent tissue regeneration times. Results showed generally faster tissue regeneration than in other studies with corals within the *Montastrea annularis* complex, some of which founds tissue regeneration times requiring months (Mascarelli and Bunkley-Williams 1999; Cróquer et al. 2002; Fisher et al. 2007).

Using a small (0.5 cm^2) lesion maximizes the possibility that the lesion will completely heal, thus preventing establishment of epibionts or disease, and allows for results to be obtained quickly. A five-day regeneration period was found to be suitable for producing enough tissue to provide a good signal-to-noise ratio but not so long as to allow complete lesion healing that would preclude quantitative assessment

M. faveolata was selected as a standardized species because of its importance to Western Atlantic reefs and its broad distribution across the province. In addition to broad distribution, *M. faveolata* is commonly found on all reef types encountered in the area and across a wide depth range. The surface of *M. faveolata* was found conducive to producing uniform lesions.

Field experiments with cores and *in situ* colonies did not find consistent differences inside or outside of the ECLSP. Two of the six assessments described (1 of 4 with cores; 1 of 2 with *in situ* colonies), did find significantly faster healing rates inside the ECLSP. Although both of these cases were in the winter months, no seasonal trends were apparent as other assessments in winter found no differences. Examination of apparent quantum yields did not reveal any effects of the lesions on adjacent tissues or seasonal effects. However, newly-formed tissues over the lesion did have significantly lower apparent quantum yields than adjacent, undamaged tissues.

To obtain useful results, the Coral Resilience Assay must be applied with special attention paid to making lesions of consistent type, size and depth (Oren et al. 1997; Hall 2001). In designing a field project, data from others strongly indicate that lesion position on the colony is important (Cróquer et al. 2002) and that colonies should be of similar size (Meesters et al. 1997) and depth (Nagelkerken et al 1999;Fisher et al. 2007).

The Coral Resilience Assay is relatively inexpensive and all necessary equipment, excluding a computer for image analysis, can be obtained for less than $500.00. Suitable image analysis software (CPCe) is available as a free download from the National Coral Reef Institute, Nova University, Dania, FL (www.nova.edu/ocean/cpce/). Scientists and resource managers are encouraged to employ this standardized lesion protocol across the Western Atlantic Province to examine coral resilience and potential stress within and between regions. A booklet with detailed descriptions of the methods and data analysis methods is available from Conservation International (www.conservation.org).

Decline of crinoids on the reefs of Curaçao and Bonaire, Netherlands Antilles

D.L. Meyer, E.A. Dame, P.B. Lask

Department of Geology, University of Cincinnati, Cincinnati, OH 45221

Abstract. Since 1996 at the latest, comatulid crinoids on the leeward reefs of Curaçao and Bonaire have declined drastically in population size and diversity. Prior to this decline, five species inhabited the forereef slope from depths of 6 to >30 m. *Davidaster rubiginosa* and an undescribed species of *Davidaster* were common from about 6 to 15 m depth, and *D. discoidea* was common below about 15 m. *Nemaster grandis* and *Ctenantedon kinziei* were found in lower abundance at about 30 m depth. Transect data from Bonaire showed that a drastic decline in numbers of the *Davidaster* taxa occurred between 1989 and 1996. Transects in Curaçao in the late 1990s through 2001 documented a similar decline. In 2007, sites in Curaçao where species of *Davidaster* were formerly common were practically devoid of crinoids. In particular, *D. discoidea*, once the most numerous crinoid in these islands, has all but disappeared. The cause of this decline on both islands is unknown. It is possible that heating associated with the severe coral bleaching event of 1995 also affected the crinoids. As far as we are aware, reef crinoid populations across the broader western Atlantic region have not shown a similar decline.

Key words: Crinoids, Curaçao, Bonaire

Introduction

Underwater censuses conducted in the late 1960s showed that five species of comatulid crinoids (feather stars) were common on the leeward fringing reefs of Curaçao and Bonaire in the Netherlands Antilles (Meyer 1973). *Davidaster rubiginosa* (Pourtalès) and an undescribed species of *Davidaster* were common along the edge of the forereef slope from about 6 to 15 m depth, and *D. discoidea* (P. H. Carpenter) was common below about 15 m. *Nemaster grandis* Clark and *Ctenantedon kinziei* Meyer occurred in lower abundance at about 30 m depth. Subsequent work in Curaçao by Liddell in the late 1970s (Liddell 1980, Liddell and Ohlhorst 1982) found similar patterns in crinoid distribution and abundance. Quantitative censuses conducted in Bonaire by Llewellyn in 1989 (Llewellyn 1991, Llewellyn and Meyer 1991) found evidence of continuing crinoid abundance. Following a hiatus in observations, in 1996 Meyer was alarmed to find an apparent decline in the numbers of crinoids in both Curaçao and Bonaire. In 1999, Lask and Meyer resurveyed the Karpata reef in Bonaire where Llewellyn had inventoried every crinoid within an area of approximately 1000 m^2 in 1989 (Lask and Meyer 2001). Llewellyn reported a total of 70 crinoids within this sampling area, but the 1999 survey found a single crinoid. Lask and Meyer (2001) revisited 13 sites in Bonaire and compared crinoid occurrence with records from these and other sites accumulated over the period 1971-1996. The comparison showed that *D. rubiginosa* had become much less common and that *D. discoidea* had totally disappeared from sites where it had previously been common (see Fig. 1). In this paper we present a similar comparison of crinoid occurrence at sites along the leeward reefs of Curaçao in the late 1960s with surveys made since 2000, and changes in population density at one site, Jan Thielbaai, that Meyer surveyed in the late 1960s.

Materials and Methods

During the period 2000 – 2007, scuba dives at 14 sites along the leeward coast of Curaçao recorded crinoid occurrence to depths of about 30 m (Fig. 2). Nine of these 14 sites had been inventoried for crinoids during the late 1960s. These dives commenced just above the top of the forereef slope at about 6 m, descended to about 30 m, followed by a short traverse at the maximum depth, and return to the shallows along an oblique course across the forereef slope. Crinoids encountered were recorded by species and depth. The total reef area surveyed at different sites was variable.

A census within an area marked off into depth zones was conducted at the Jan Thielbaai site in 1968 – 69 (Table 1, Meyer 1973). This census extended from a depth of 8 m along the top of the forereef slope to 38 m and covered a total area of 1905 m^2. Crinoids were

recorded within marked depth intervals and the results were plotted as bathymetric changes in population density. In 2001 and 2007 a large areal census at this site was not repeated, but several strip transects were inventoried at different depths parallel to the reef slope at the same location of the earlier survey. In 2001, two transects each 50 m long were surveyed at two depths 10 m and 15 m, with two divers each surveying a band one meter above and below the tape, for a total of 200 m^2 per transect. In 2007, the census followed the AGRRA protocol of six transects, each 1 m wide by 10 m long, at a depth of 8 m along the top of the reef slope (Ginsburg 2005). Crinoids were also inventoried at Jan Thielbaai during 2000 – 2007 on several dives to about 30 m that did not control for survey area.

Results

In 1968-69, the most common crinoids, *Davidaster rubiginosa* and *D. discoidea*, could be found at most sites along the leeward reefs of Curaçao (Fig. 2) as well as Bonaire in 1971 (Fig. 1). At that time the undescribed species of *Davidaster* was considered to be an intraspecific variant of *D. rubiginosa*. Therefore the records of occurrence for *D. rubiginosa* for 1968-69 include forms now regarded to be a separate species. Only at the Jan Thielbaai site do photographic records and the tally of distinct variants of *Davidaster* (Table 1) provide a definite record of the undescribed species in 1968-69. Surveys conducted from 2000-2007 revealed that both *D. rubiginosa* and *D. discoidea* have declined in occurrence in Curaçao as they have in Bonaire (Fig. 2). One or both species have disappeared from several sites where they occurred in 1968-69.

The presence/absence data in Figure 2 alone do not convey the drastic decline in crinoid populations on the Curaçao reefs. Beginning in 1996, it was apparent that crinoid abundance was conspicuously reduced in Curaçao as it was in Bonaire (Lask and Meyer 2001). In 2001, we resurveyed the Jan Thielbaai site where Meyer had conducted a census of population density in 1968-69 (Table 1). Transects along the reef slope at 10 and 15 m covered depth intervals where crinoids had maximum density in 1968-69. *D. discoidea* was absent from these sampling areas, and both *D. rubiginosa* and *Davidaster* n. sp. were greatly reduced in numbers. *Nemaster grandis* was encountered in low numbers at 10 and 15 m, where it had been rare historically. This species was observed in greater numbers around 30 m depth. Although we were unable to obtain population density data at depths below 15 m, the *N. grandis* population appeared to be at levels similar to 1968-69. We revisited the site in 2002 2003 2004, and 2005, and found the same three species to be present. In 2007 we conducted an

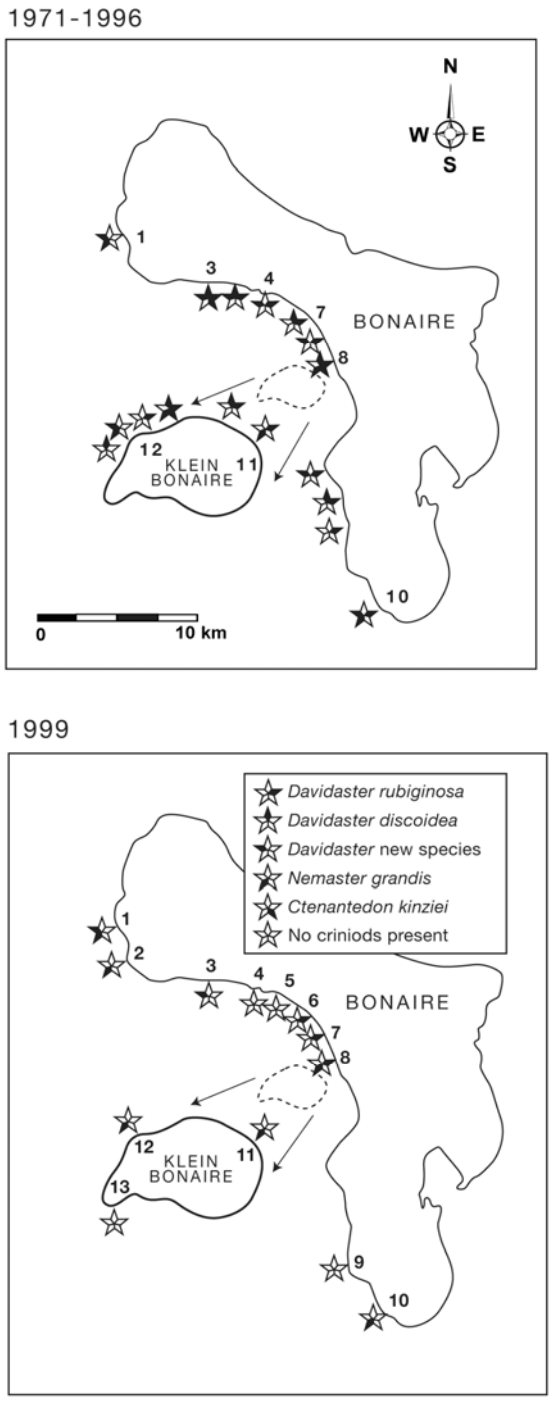

Figure 1: Crinoid species distribution at sites in Bonaire surveyed in 1971-96 (left), and in 1999 (above). Species occurrence is indicated by a black infilling of each of the five segments of the arrow symbol as shown in the legend. Modified after Lask and Meyer (2001).

AGRRA survey at Jan Thielbaai which included a series of transects at 8 m depth along the top of the reef slope. Although crinoids had not been very

common at 8 m historically, we were surprised not to encounter any crinoids at all in those sampling areas. In 2007 we also conducted AGRRA transects at Slangenbaai, another site where crinoids were very common in 1968-69. No crinoids were encountered within 6 transects, each 1 x 10 m, parallel to the reefslope at 8-10 m depth. Two individuals of *Davidaster* n. sp. were encountered outside these sampling areas at about 10 m depth. Clearly the population density of crinoids at this site was also drastically reduced from levels observed in 1968-69.

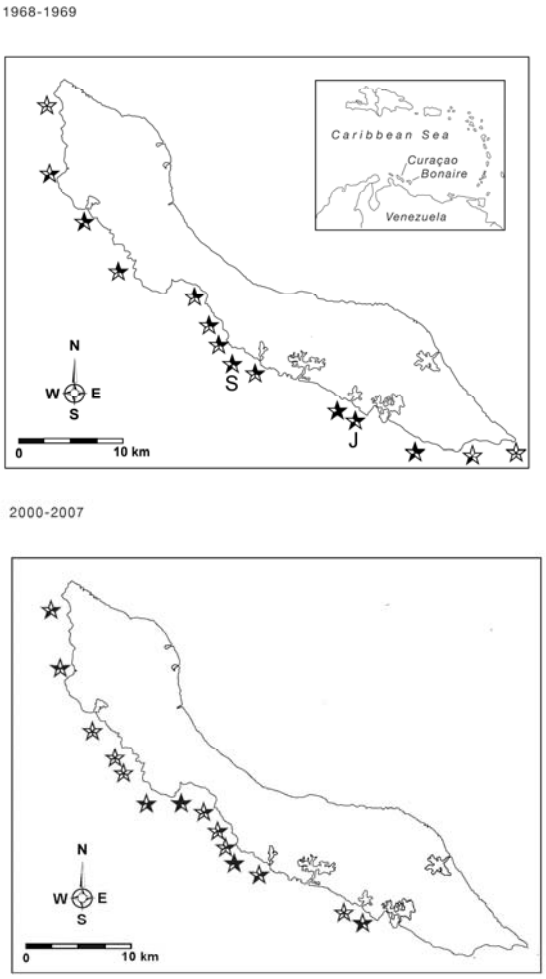

Figure 2: Crinoid species distribution at sites in Curaçao surveyed in 1968-69 (bottom of left column), and in 2000-2007 (above). Species occurrence as in Fig. 1. J = Jan Thielbaai, S = Slangenbaai.

Discussion

An alternative hypothesis is that the observed decline since the early to mid-1990s represents part of a long-term cyclical fluctuation in crinoid populations, occurring on a timescale greater than the 40 yr span of underwater observations of crinoids in the Netherlands Antilles. Although such a possibility cannot be discounted, we feel it is unlikely given the apparent stability in crinoid populations from the late 1960s until the mid-1990s. The possibility that the timing of our surveys could have coincided with some short-term seasonal fluctuation in crinoid populations is also unlikely because surveys prior to 1996 when crinoids were more numerous usually occurred during the summer, and surveys after the mid-1990s drop in crinoids were also taken in the summer months.

The exact timing and cause of the decline in crinoids on the leeward reefs of Curaçao and Bonaire remain unresolved. We know that the decline occurred between 1989 and 1996, but we do not know where or when the decline started or how rapidly it progressed, as there was a six-year hiatus in our visits to the islands. By 1996 it appears the decline was well underway as we did not observe any recently dead

crinoids in 1996. Because crinoids decay and disarticulate within a few days after death, it is likely that skeletal remains of crinoids would be rapidly dispersed in the reef sediments (Meyer and Meyer 1986). Unless an observer encountered moribund crinoids directly, it is quite possible that a mass die-off could pass unnoticed. In 2000, Lask observed a single moribund individual of *D. rubiginosa* at 11 m depth at one site in Curaçao, but was unable to obtain further information about the cause of this condition. The crinoid die-off may have followed a pattern similar to that of the mass mortality of the reef-dwelling echinoid *Diadema antillarum* (Bak et al. 1984). Meyer observed scores of moribund and recently dead echinoids when the mass mortality occurred in Bonaire in November 1983. By August of 1984 the skeletal remains of enormous numbers of echinoids had been effectively dispersed into the reef sediments (Greenstein 1989).

It is noteworthy that the crinoid decline occurred in both Curaçao and Bonaire. Curaçao has a human population about an order of magnitude higher than that of Bonaire, accompanied by a much higher degree of industrialization and coastal development. In contrast, Bonaire has little industrialization but increasing levels of coastal development. The entire fringing reef of Bonaire, contained within the Bonaire Marine Park, is one of the world's best-protected reef tracts. Because Curaçao usually lies downstream from Bonaire in the path of the Caribbean Current, pollution outfall from more-developed Curaçao will most likely be carried westward. Occasional reversal of the normal westerly flow could carry pollutants from Curaçao to Bonaire. It should also be noted that despite the increased likelihood of anthropogenic impacts on the Curaçao reefs, two sites where crinoids were surveyed, Jan Thielbaai and Slangenbaai, were both treated as control sites with little or no upstream coastal development in Nagelkerken's 2006 study of human impact and bleaching-related coral mortality.

One possible environmental perturbation that could have affected the crinoid populations on both islands was a protracted interval of seawater temperature elevation in late 1995. This thermal stress resulted in widespread coral bleaching and subsequent mortality along the leeward reefs of Curaçao and Bonaire (CARICOMP 1997; Nagelkerken 2006). In 1996, Meyer observed the ongoing effects of this bleaching as partial mortality and incipient recovery of coral colonies. Seawater surface temperature data reported by Nagelkerken for several sites along the leeward coast of Curaçao, including Jan Thielbaai, showed that temperatures rose in August and attained a maximum close to 30 deg. C by late September, returning to normal levels by late December. Although the physiological tolerance of comatulid crinoids for elevated temperatures is not well known, it is quite likely that many crinoids could have succumbed to this thermal stress. The fact that crinoids previously common along the shallower parts of the forereef slope, from 6- 15 m, seem to have been most severely reduced in numbers is consistent with heating of the shallow part of the water column. Deeper populations of *N. grandis* at about 30 m depth apparently persisted in numbers comparable to those observed in 1968-69, insofar as our limited opportunities to assess them have permitted. A thermal cause is consistent with crinoid decline at sites along the leeward coasts of both Curaçao and Bonaire. Other, as yet unidentified causes for the crinoid decline should not be discounted. For example, the outbreak of the aspergillosis epizootic among sea fans also occurred in the Netherlands Antilles reefs in 1995 (Nugues and Nagelkerken 2006), just before the decline in crinoids was first noted.

As far as we are aware, the decline in reef crinoids in the Netherlands Antilles has not occurred over the broader region of the tropical western Atlantic. Causey (2008) reported that no crinoids were found during a survey in 2001 on Looe Key Reef in the Florida Keys where they had been seen frequently in the 1960s and 1970s; however, crinoids are still seen on reefs of the Dry Tortugas. Meyer photographed both *D. rubiginosa and D. discoidea* on Molasses Reef in the Florida Keys in 1981 (unpublished observations). According to recent reports crinoids are still abundant in such places as St. John, Virgin Islands (C. Rogers, personal communication to DM) and Jamaica (T. J. Goreau, personal communication to DM).

As rheophilic suspension feeders, crinoids may be sensitive to different environmental changes than reef-building corals and other macroinvertebrates. Because crinoids were once among the most common suspension-feeding macroinvertebrates on these reefs, their rapid decline is a cause for concern. Ongoing monitoring of their population fluctuations could provide a different and potentially informative indicator of the overall health of the reef community.

Abstract. Limited information currently exists on the recovery periods of bleached corals as well as the spatial extent, causative factors, and the overall impact of bleaching on coral reef ecosystems. During October, 2005, widespread coral bleaching was observed within Buck Island Reef National Monument (BUIS) St. Croix, USVI. The bleaching event was preceded by 10 weeks of higher than average water temperatures (28.9-30.1°C). Random transects (100 m^2) over hard bottom habitats (N=94) revealed that approximately 51% of live coral cover was bleached. Nineteen of 23 coral species within 16 genera and two hydrocoral species exhibited signs of bleaching; species-specific bleaching patterns were variable throughout the study area. Coral cover for *Montastraea annularis* and species of the genus *Agaricia* were the most affected, while other species exhibited variability to bleaching. Although a weak but significant negative relationship (r^2=0.10, P=0.0220) was observed, bleaching was evident at all depths (1.5-28 m). Bleaching was spatially autocorrelated (P=0.001) and hot-spot analysis identified a cluster of high bleaching stations northeast of Buck Island. Bleaching was significantly reduced within all depth zones and habitat types upon subsequent monitoring during April (15%) and October (3%) 2006.

Key words: Coral Reef, Coral Bleaching, USVI, Buck Island.

Introduction

During June to October 2005, a significant coral bleaching event took place ranging throughout the Caribbean and the southeastern U.S. Satellite sea surface temperature data indicated that the thermal stress associated with this warm water was the highest experienced during the previous 20 years (NOAA Coral Reef Watch, http://coralreefwatch.noaa.gov/caribbean2005/, accessed 7/02/2008). In October 2005, data on extent and severity of the coral bleaching were recorded during the biannual monitoring of coral reefs in St. Croix, US Virgin Islands conducted by scientists from NOAA's Center for Coastal Monitoring and Assessment's Biogeography Branch (CCMA-BB) and the National Park Service's Buck Island Reef National Monument.

This study quantifies spatial patterns of coral bleaching observed along the northeastern shore of St. Croix comprised of habitats within and adjacent to BUIS and the northern portion of the East End Marine Park (EEMP) during October 2005 through October 2006 (Fig. 1.). Specific objectives include:

1) describing the extent, severity and spatial patterns of coral bleaching before, during and after the 2005 bleaching event
2) correlating coral bleaching with environmental factors such as *in situ* temperature and depth
3) describing taxonomic differences in the severity of bleaching experienced by different coral species.

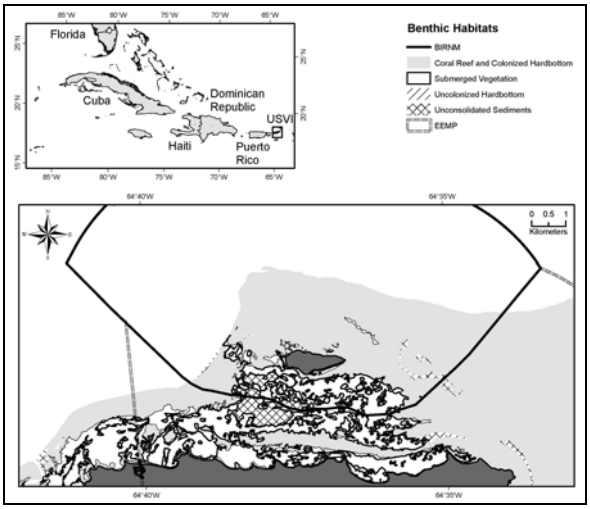

Figure 1: Map of study area around Buck Island Reef National Monument. BIRMN = Buck Island Reef National Monument; EEMP = East End Marine Park.

Material and Methods

Data on benthic composition were recorded from five $1m^2$ quadrats along randomly selected 25×4 m belt transects (100 m^2) as part of a larger project that surveyed 2,790 sites to characterize and monitor fishes and benthic composition in coral reef ecosystems in the US Virgin Island and Puerto Rico between 2001 and 2006. Survey sites were selected using a stratified random sampling design (Menza et al, 2006). Colonies were considered entirely bleached if they contained white, blotchy/mottled, or pale tissue (Fig. 2.). In situ water temperature data were obtained for January 1999 - December 2006 from a single data logger located at 10 m on the fore-reef at BUIS. Linear regression was used to examine the relationship between depths of sites and proportion of total coral cover bleached at each site. Autocorrelation of spatial bleaching patterns was tested using Moran's Index and Geary's C statistic. Time series plots of the proportion of live coral that was 'normal' or 'bleached' from October 2005 through October 2006 examined temporal trends in coral bleaching.

Figure 2: Bleached colony of *Acropora palmata* observed in the study area during October 2005. Quadrat in frame is $1m^2$, with 10cm x 10cm divisions.

Results

From October 2005 through October 2006, 27 scleractinian coral species within 21 genera and two species of fire coral were observed within 294 transects. Water temperatures were consistently higher during the study period when compared with the eight year mean (Fig. 3.).

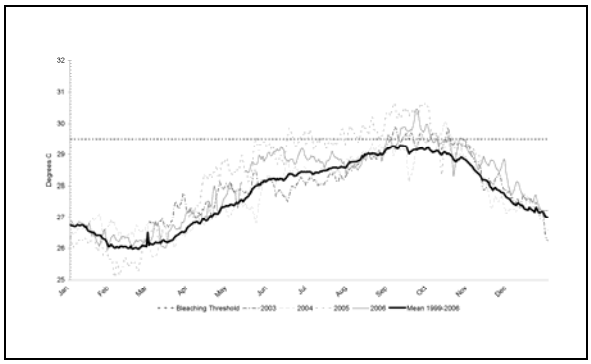

Figure 3: In situ water temperature from the forereef (10m) of BUIS 2003 – 2006. Flat dashed line is bleaching threshold (29.5^0C). Data provided by NPS.

During 2005, mean water temperature was significantly greater ($p<0.0001$) for each summer/fall month (Jun-Oct) than all other years.

October 2005

Mean percent of live scleractinian and fire coral cover (per 100 m^2) ranged from 0.96% on reef rubble to ~ 6% on linear and patch reefs. Surveys (n=94) identified 23 scleractinian coral species (16 genera) and two hydrocoral species. Bleached corals were observed at 91% of all transects (Fig. 4.). Bleached colonies were completely white, with few being mottled or pale. Fifty-one percent of the total coral cover within transects was bleached, and species-specific bleaching proportions ranged from 15.8-100%.

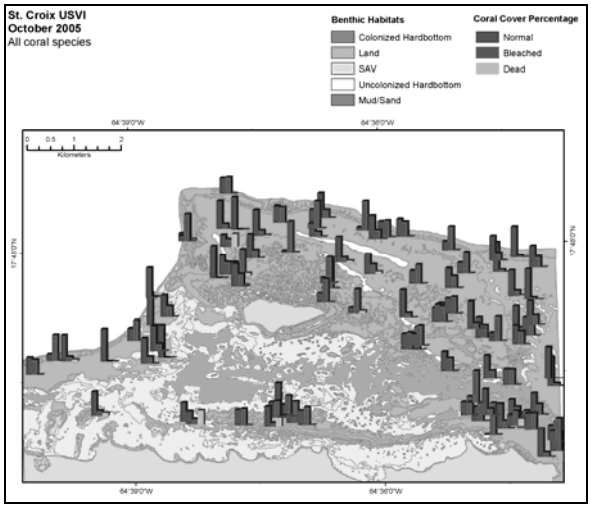

Figure 4: Coral cover percentages of all coral species that were observed as normal (showing no signs of bleaching or discoloration), bleached or dead at each site during October 2005.

April 2006 – Post Bleaching

Bleaching was significantly reduced ($p<0.0001$) throughout the study area during April 2006 vs. October 2005. Surveys (n=89) identified 31 species of

coral where 15% of total coral cover exhibited bleaching (Fig. 5.). Most colonies were mottled/pale, except *Agaricia*, which were completely bleached. Fifteen species exhibited no bleaching affects. Colonies of *M. annularis* and *D. strigosa* were less bleached than those observed in October 2005. *Agaricia* cover was less bleached (16%) than observed in October 2005 (92%). Only two species had bleaching percentages greater than 50% (*Millepora complanata* and *D. labyrinthiformis*) but were infrequently encountered. Overall, nearly all species showed a dramatic decrease in bleached cover within all depth zones.

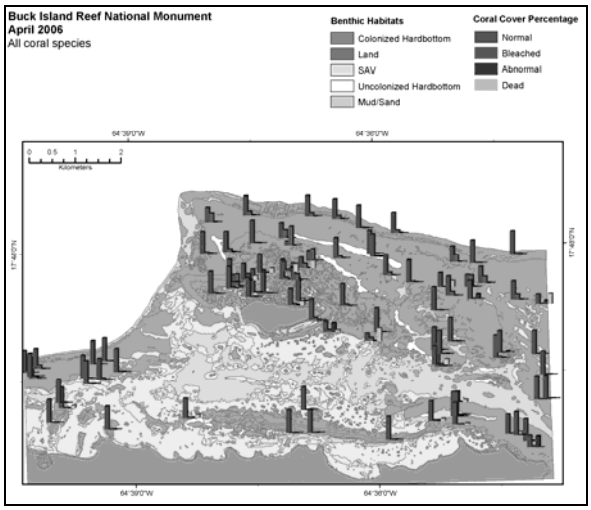

Figure 5: Coral cover percentages of all coral species that were observed as normal (showing no signs of bleaching or discoloration), bleached or dead at each site during April 2006.

October 2006 – One Year Post Bleaching

Bleaching was significantly lower ($p<0.0001$) than during the two previous sampling periods. Surveys (n=93) identified 20 scleractinian coral (5 genera) and two hydrocoral species. Bleaching was evident in 14% of transects with 3% of the total coral cover bleached. Most species exhibited significant declines in bleached cover within all depth zones compared to October 2005 and April 2006 (Fig. 6.). Dramatic decreases were observed for *M. annularis*, *P. asteroides*, *Agaricia*, *P. porites*, and *D. strigosa*.

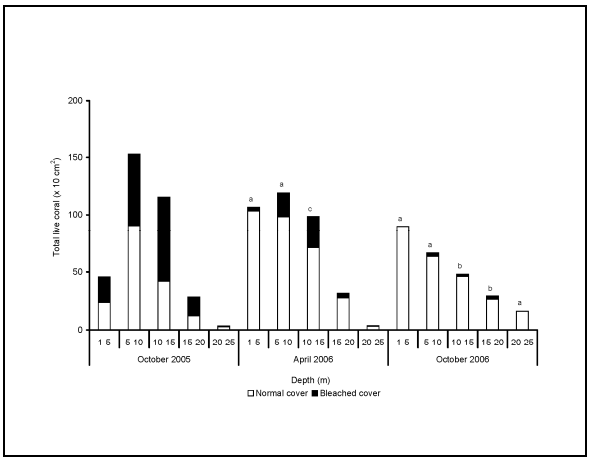

Figure 6: Normal and bleached coral cover within depth zones during study period. a=statistically different from Oct 2005; b=statistically significant from Oct 2005 and Apr 2006; c=statistically significant from Oct 2005 and Oct 2006. All at alpha=0.05.

Discussion

Bleaching events may alter the abundance of functional groups and their component species and have profound effects on the ability of local communities within the ecosystem to resist and recover from future disturbances. A better understanding of these indicators may help managers identify, design and manage protected areas to promote reef ecosystem survival. Results here provide evidence that bleaching has differential effects to the coral community; it is unknown what degree these effects have upon reef community structure. Understanding reef degradation (i.e. coral bleaching) at various scales and the potential for recovery should be a priority for scientifically based conservation and management plans.

Acknowledgement

This study was made possible by the dedicated efforts of the CCMA and NPS staff and was funded by CCMA, NPS and NOAA's Coral Reef Conservation Program.

Abstract. The Mesoamerican Barrier Reef System (MBRS) comprises coral reefs in Mexico, Belize, Guatemala and Honduras. The Synoptic Monitoring Program (SMP) was developed to assess the coral reefs and associated ecosystems. This program is currently applied in most of the MPAs in the region. It includes sites selected within MPAs that represent strategic sites (Take and No take sites) for park managers on the back reef, shallow (5-12m) and deep fore reef (14-20 m). In 2004, the MBRS region had an average live coral cover of 23%; within a range that is generally considered to be healthy. The maximum coral cover was 50% on deep fore-reef sites, while 2% was the minimum cover at shallow fore-reef sites. The mean cover numbers indicated that the 3 main habitats were relatively healthy. Fish site density averages 34.7 fish per $100m^2$ with ranges from 5.0 to 110.6 ind./$100m^2$. The coral cover had decreased from 23 to 13% in only 4 years in the MPAs, the most dramatic loss of coral was in 2005, with an average loss of 2% in each of the next 3 years. Although monitoring is not equal in all countries and each MPA had different sample sizes, the MBRS region have a generalized coral cover decrease tendency.

Key words: Mesoamerican Reef, Coral Reef, Coral Cover, Status, Monitoring.

Introduction

The Mesoamerican Barrier Reef System (MBRS) comprises coral reefs in Mexico, Belize, Guatemala and Honduras (Arrivillaga and Garcia 2004); it extends more than 1,000 km in Caribbean waters of those four countries (McField and Kramer 2007) and has been considered one of the greatest biodiversity points in the Caribbean (Roberts et al. 2002). The MBRS contributes to the stabilization and protection of the coasts, maintain coastal water quality and serve as feeding and nursery habitats for many marine organisms which have great commercial importance (Almada-Villela et al. 2003).

Major threats in the region are the destruction of natural coastal habitats by increasing coastal population and tourism developments, and increased sedimentation due to extensive and unsustainable use of watersheds and inland deforestation (Arrivillaga and Garcia 2004). The MBRS Project carried out from 2004 to 2008 as a regional cooperation between Mexico, Belize, Guatemala and Honduras had the objective of developing actions focus on the conservation and sustainable use of the system.

The MBRS Synoptic Monitoring Program (SMP) was developed to standardize the assessment of coral reefs and associated ecosystems in marine protected areas (Almada-Villela et al. 2003). The information is targeted at natural resource managers by providing the status and trends in the marine and coastal resources. This article includes a brief summary of the baseline (2004) data for the Coral Reef Ecosystem Results of the SMP for the region and the Status for 2008.

Material and Methods

The Mesoamerican Barrier Reef System (MBRS), is one of the longest reef developments in the Western Hemisphere (Fig. 1), it extends over 1000 km from

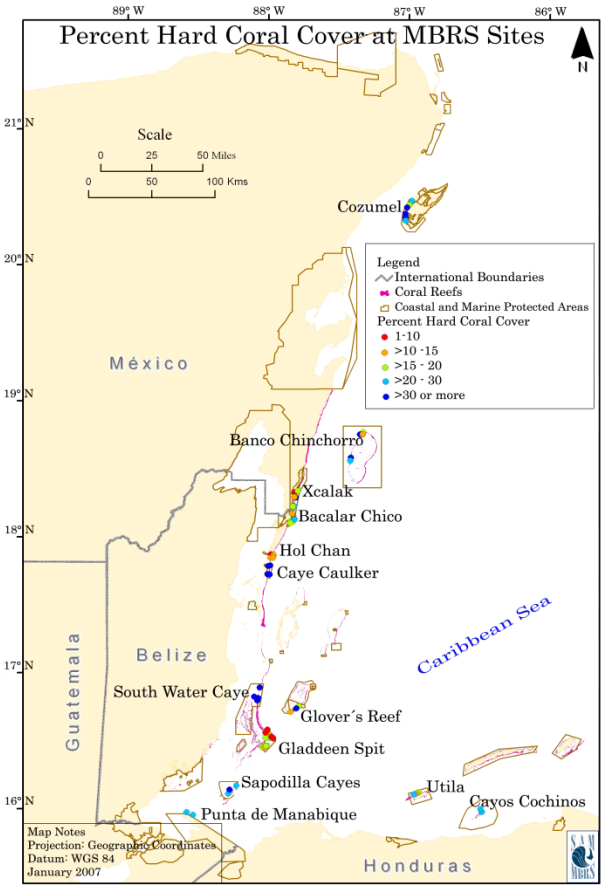

Figure 1. Marine Protected Areas in the Mesoamerican Barrier System included on the SMP. Different color points indicate percent of hard coral cover in each site. See legend on the frame.

Yucatan in Mexico, through Belize to the Bay Islands in Honduras (Mcfield and Kramer 2007).

The Synoptic Monitoring Program (SMP) of the MBRS project was developed based on different methods already used for the region (Almada-Villela et al. 2003). To define sites for the purposes of the SMP, terminology and procedures followed those of Woodley (1999) except that it uses *Location* instead of *Area* (Almada-Villela et al. 2003): Each *Location* contains *Sites* distributed in one or more *Habitats*: shallow back-reef (1-5 m), shallow fore-reef (5-12 m) and deep-fore reef (14-20 m). Most *Locations* are situated in Marine Protected Areas except for Akumal in Mexico. Sites were selected strategically based on particular interest to local management (i.e. sites for use or non-take zones). The data assessed here includes results of reef monitoring carried out from 2004-2008 at *Location* level in each of the four countries.

From North to South assessed *Locations* were located in Mexico, at reefs of Cozumel, Akumal, Banco Chinchorro and Xcalak; in Belize, at reefs located at Bacalar chico, Hol Chan, Caye Caulker, South Water Caye, Gladen Spit, Sapodilla Caye and Port Honduras; Punta Manabique reef in Guatemala; and Utila, Cayos Cochinos and Sandy Bay reefs in Honduras. Protocol for coral reef monitoring includes three components: a) benthic cover, b) coral colonies condition and c) fish community.

a) Benthic cover was assessed in five 30m transects by point intercept transect method including benthos components in each of the following categories: hard coral (to genera), sponges, algae, calcareous algae, soft coral, other living organisms, rock and sand.
b) Colonies of hard coral are identified to species measuring maximum diameter and height. Condition is evaluated by percentage of recent and old mortality and percentage of diseases, bleaching and other stresses.
c) Methods for fish evaluation are based on the AGRRA protocol. Census of 8 indicator families and selected species (www.agrra.org) are conducted using 8 belt transects of 30x2 m. Individuals are identified to species and classified based on size classes.

Number of *Sites* was variable among *Locations* due to the differences interests and objectives of managers (Table 1). SMP was a regional effort applied in each country depending on the management capacity (logistics, staff, resources, etc.) of each MPA.

In order to establish a first baseline of the status of the MBRS for future comparisons, the average value for the parameters recorded in each location along the MBRS was related to a condition category scaled for each component. After stony corals, algae are considered the most prevalent component of the reef benthic community. So coral and algae cover were divided into five categories based on ecological status (Table 2). These categories have been determined based on their relevance to management followed by general recommended actions.

Results

Baseline 2004-2005

Mexico

In 2004, there was 24% average coral cover in the three MPAs: Xcalak, Banco Chinchorro, and Cozumel Island. The lowest (18%) was in Xcalak with higher algal cover (41%), which indicates 'alert' status, similar to that in Cozumel with less coral cover (27%) than algal cover (32%).

Table 1. Sites monitored and sample size in numbers of transects for the benthic component by MPA.

Country	MPAs	Sites	Maximum number of transects+	2004	2005	2006	2007	2008
Mexico	Akumal	12	60	-	-	5	113*	30
	Banco Chichorro	8	40	37	-	-	34	25
	Cozumel	6	30	30	30	30	30	-
	Xcalak	6	30	30	-	58*	3	-
Belize	Bacalar Chico	5	25	20	22	10	15	-
	Caye Caulker	4	20	20	20	20	16	-
	Gladden Spit	10	50	41	63*	5	47	-
	Glover's Reef	3	15	-	15	-	-	-
	Hol Chan	4	20	-	20	40*	40*	-

	Sapodilla Cayes	3	15	15	15	20*	12	-
	South Water Caye	4	20	20	5	-	-	-
Guatemala	Punta Manabique	2	10	10	10	-	-	-
Honduras	Cayos Cochinos	5	25	25	25	25	25	-
	Sandy Bay	5	25	-	-	-	23	-
	Utila Island	3	15	-	15	15-	-	-

+ The numbers of transects were standardized to five by site, because in some localities found more than six.
* Some sites were monitored two times along the year.

However, on Banco Chinchorro conditions were considered to be 'optimal' with less algal abundance (23%) than coral cover (27%). The average diameter of coral colonies from the country (31 cm) was according to the average of the entire MBRS region (33 cm). The most common reef fish species were from Family Acanthuridae, mainly in Banco Chinchorro and Xcalak. Cozumel had the second highest fish densities for the region and Banco Chinchorro have the largest algal grazing (herbivore) population living on the deep fore reef. Akumal started SMP until 2006 so the results were not integrated on the baseline in 2004.

Belize

Average coral coverage was 26%, this coral cover is acceptable in relation to the average of the entire MBRS region from 23 to 26% (García-Salgado et al. 2006; Kramer 2003). Although the country has a general 'good' status, three MPAs had more than 40% algal cover and lowest coral cover: Bacalar Chico was considered to be 'alert' status (less than 19% of coral cover), Hol Chan and Gladden Spit were in a 'poor' condition (11% of coral cover). The diameter of coral colonies, however, was greater than in all other countries (maximum 70 cm). The lowest populations of coral reef fishes were found in Caye Caulker and Gladden Spit; whereas Bacalar Chico Location had the most abundant species of herbivores (Acanthuridae, Scaridae) on the deep fore reef.

Guatemala

Only two sites in the Punta de Manabique MPA were monitored. The small reef patches had an average coverage of 26% with the sediment-resistant species (*Montastraea cavernosa, Siderastrea siderea, Agaricia* spp.) being most common. These reefs patches experience high sedimentation and river discharge that impedes coral growth, and possibly also reduces algal growth due to poor light penetration; low algal cover of 25% was measured according to the average of the entire MBRS region (35%). These patch reefs may serve as reference sites as the first reefs to be affected by human activities, such as sedimentation, nutrient loading, harmful chemicals, and solid waste.

Honduras

Utila Island and Cayos Cochinos Locations include similar reef structures as island platforms with an average depth of 5 m, culminating in a steep slope. Utila Island has low coral coverage (16%) and is considered to be in 'alert' status, whereas Cayos Cochinos was in good condition with 24% average coral cover. This Location had the most abundant number of species of herbivore fishes (Scaridae, Acanthuridae) from the locations evaluated in Honduras, however, both Locations (Cayo Cochinos and Honduras) have a critical level of algal cover (> 40%).

Status 2007- 2008

Although monitoring is not equal in all countries and each MPA had different sample sizes, on average coral cover has decreased by 10% in only 4 years. The year with the highest decline in coral cover was 2004-2005 with a maximum of lost in Mexico (11%) and an average in the MBRS region of 7%. In the next years the coral cover show a great variability between MPAs, even though throughout the region had an average loss of 2% (Fig. 2).

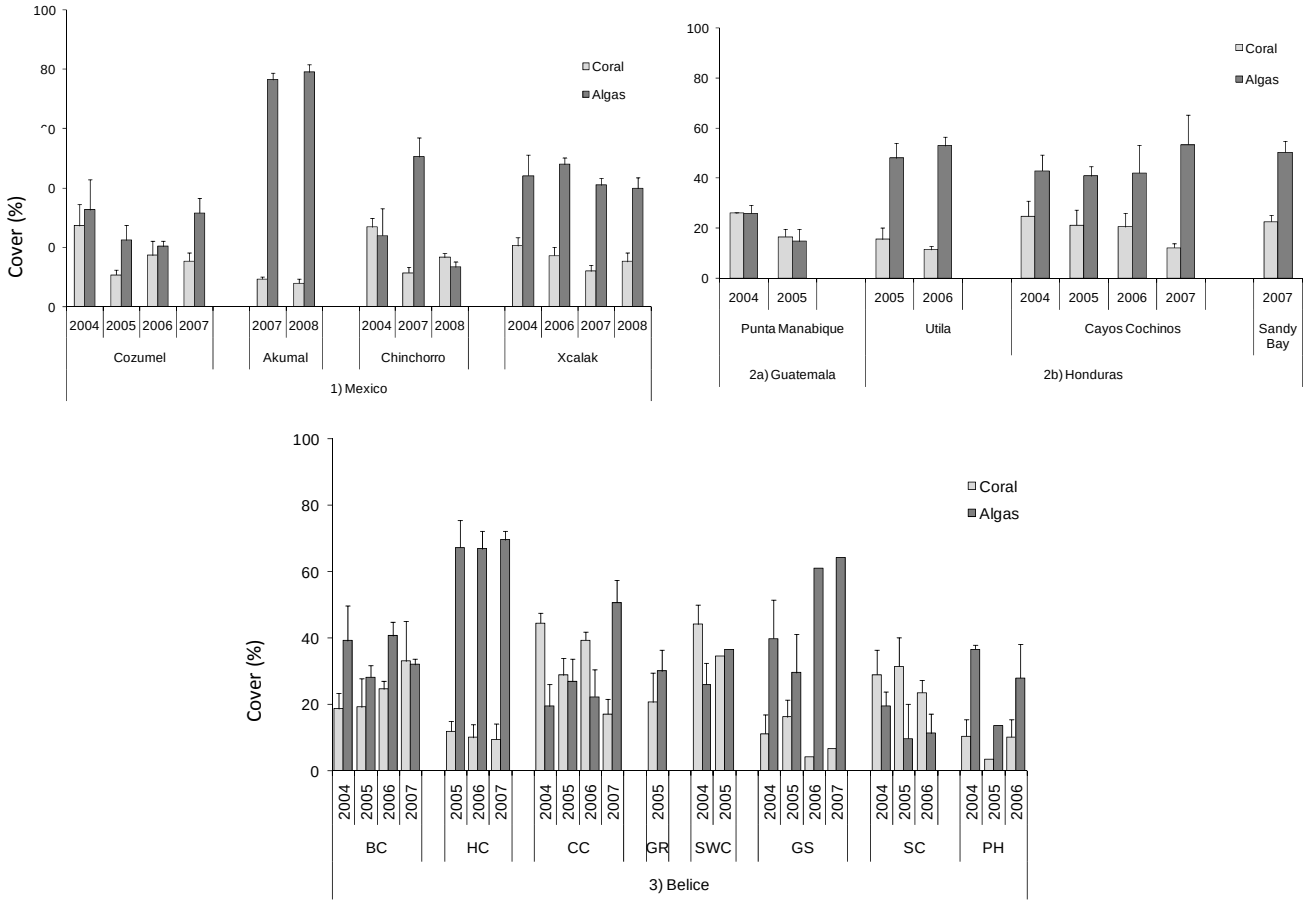

Figure 2: Coral and algal coverage trends in the MBRS with standard deviation. 1) Mexico, 2a) Guatemala, 2b) Honduras and 3) Belize (BC, Bacalar Chico; HC, Hol Chan; CC, Caye Caulker; GR, Glovers reef; SWC, South Water Caye; GS, Gladen Spit; SC, Sapodilla Caye and PH, Port Honduras).

Mexico

All MPAs in Mexico report a decrease in coral cover and an increase of algal cover. Reefs in the region were damaged by hurricanes Emily and Wilma in 2005, Beta and Gamma storms at the end of the same year and hurricane Dean in 2007 with direct loss of live coral cover and variations in fish densities. Parallel, increases in algal cover were variable; for example, in Banco Chinchorro the algal cover increased from 24% in 2004 to 50% in 2007 and then dropped to 15% in 2008, possibly as to physical removal from Hurricane Dean in 2007; as reported in other hurricanes (Lapointe *et al.* 2006). The Akumal Location was added to the monitoring program in 2006 and the first surveys showed low coral cover (mean 10%) and high algal cover (mean 75%); so it was considered to be in a 'critical' status.

Belize

Coral cover in Bacalar Chico MPA had increased by 14% (in 2004 the coral cover was 18% and in 2008 was 33%), with fluctuations in the algal coverage. In 2004 this site was considered as 'alert' status; by 2008 it was regarded as being in good condition. The other MPAs in Belize showed a generalized decrease tendency in coral cover and an increase in algal cover. Unfortunately, Hol Chan and Gladden Spit were regarded as being in a 'critical' condition because these MPAs had less than 10% of coral cover and more than 60% of algal cover.

Guatemala

Monitoring in Guatemala had covered only 2 years, with a same tendency for coral and algal coverage to decrease from 26% and 25% to 16% and 14%, in each component. These tendencies showed a generalized loss of biotic component cover of reefs ecosystem.

Honduras

The Sandy Bay MPA was added to the monitoring program in 2007 with coral cover of 22% and algal cover of 50%. Utila and Cayos Cochinos showed a decrease tendency in coral cover. On Cayos Cochinos

Table 2. Scale for condition category in algae and coral components for MBRS locations. Cover percentage limits for each of the five categories: Critical, poor, alert, good and optimal.

Category	Coral Cover		Algae Cover		Action recommended
	From (%)	To (%)	From (%)	To (%)	
Critical	1	10	>50	-	Stress agents must be determined in order to propose mitigation and/or restoration actions. These sites will also require more effficient management and the feasibility of closing the site to all types of activities must be considered.
Poor	10.01	15	40.01	50	
Alert	15.01	20	30.01	40	Possible stress agents (pollution, nutrient loading, herbivorous decreased) need to be determined in order to propose preentive actions and avoid deterioration
Good	20.01	30	20.01	30	Continue monitoring to detect possible changes on coral and algae cover correlations, live components should be surveyed and herbivores fish protected to keep algal growth low in coverage.
Optimal	>30.01	-	1	20	

the coral cover dropped by approximately 50%, in 2004 it was 24%, and in 2008 the cover was only 12%. Meanwhile in Utila the decrease of coral cover was from 15 to 11%.

Status of fish community

Fish monitoring showed temporal variation between the two semesters of the year (Table 2) along the MBRS region. In Mexico (Fig. 3), Akumal, which lacks of a legal protection, did not have significant changes since 2006, but had the lowest density below the baseline regional average registered in 2004. Banco Chinchorro maintained high values for fish abundance, with the higher densities of families Acanthuridae, Scaridae and Serranidae. In Cozumel, immediately after Hurricanes Emily and Wilma (2005-2) densities reached far beyond the average (72 ind/100m^2) probably due to a temporary redistribution of individuals into non-damaged habitats (Lassig 1983; Walsh 1993), changes in feeding sites and a higher activity of the individuals (Kaufman 1983) as well as for the presence of large carnivores possibly due to redistribution of habitats (Kaufman 1983; Letorneur *et al*. 1993). The effects of the storms were observable until 2006 with a reduction in fish abundance. However, the following year (2007) an increase in density could be observed for families Haemulidae and Pomacentridae.

Protection on the National Park in Xcalak had a positive effect on fish populations according to the baseline data from 2004 to 2006 which could be a consequence from the application of the management program in 2004. A similar situation to that in Cozumel appeared to occur in Xcalak after hurricane Dean (2007-2) which affected the southern most part of Quintana Roo. Density increased above the average (60 ind/100m^2) followed by a considerable reduction in the first period of 2008 (44 ind/100m^2). Values were still above the regional average but carnivores (Serranidae and Lutjanidae) remained with low values.

Gladen Spit and Caye Caulker in Belize (Fig. 3) had the lowest densities and appear with no significant changes in 2007. Nevertheless in Bacalar Chico fish abundance kept values above the average during 2004, 2005, 2006, dropping in 2007 less than the baseline average (22 ind/100m^2). Hol Chan and Sapodilla Caye were localities in Belize with the higher densities in 2007 (77 ind/100m^2). These reefs showed seasonal variations throughout the years with a major decline in fish abundance during the second period of 2006. This reduction was probably due to the effect of 2005 hurricanes and 2006 first tropical storms in the region but then a considerable increase was noted the following year (2007). Cayo Cochinos in Honduras showed a decreasing trend from 2004 to 2007. Other sites of Honduras could not get enough data for temporal comparison.

Discussion

The MPAs evaluated in the MBRS region shows a generalized trend of decrease coral cover. The most evident loss was reported in the 2004-2005 years (7%); in the subsequent years these tendencies are in the range of 2%. These decreases were largely measured in localities under protection status, which may then represent a more serious coral loss throughout the whole region. The Healthy Reefs Initiative (2008) have shown that even MPA sites monitored here had higher reef health (especially higher coral cover) than the reef in general as measure by the 332 sites in the Report Card.

The results in the SMP in sites under protection status showed effects of perturbation. It seems that strategies have apparently not been sufficient for buffering

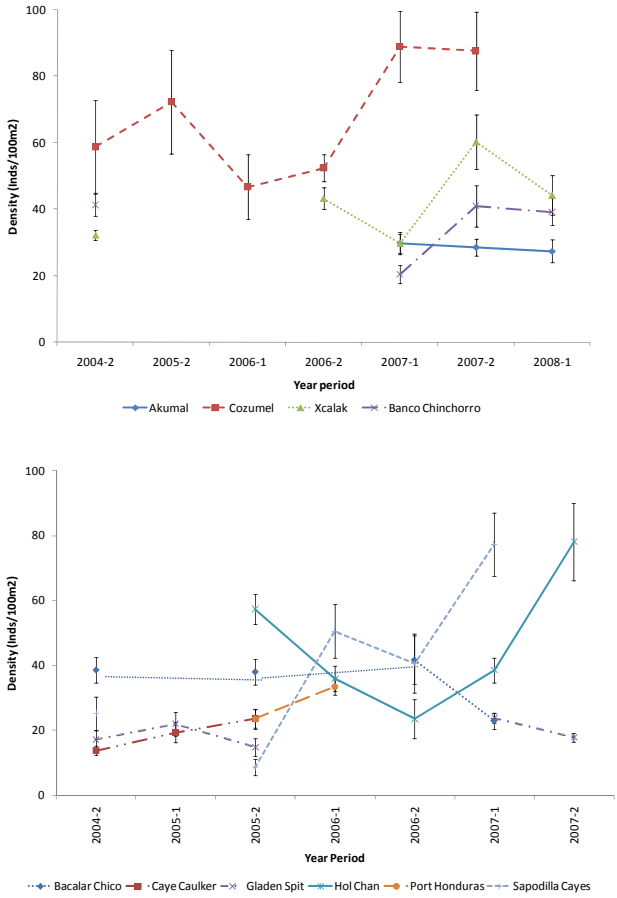

Figure 3: Average fish density (Inds/100m^2) and standard error bars by year (2004-2008) and semester (1-2), in Mexico (upper) and Belize (lower).

the different and constant types of impacts in the region like hurricanes and local structural modifications in the resources as well as conditions in the whole coral reef ecosystem (Nava-Martínez y Alvarez-Filip 2005; Wilkinson and Souter 2008). Thus management strategies have apparently not been the sufficiently effective to attenuate the increasing negative impacts in the reefs. While some of these impacts were natural and therefore difficult to predict, damaging human activities are strongly implicated. The management strategies will have to improve and adopt the precaution principle to mitigate damaging human activities and to improve resilience against natural impacts. Fish resources are coming under greater pressures from increasing tourist development with some species, mainly groupers (Serranidae), snappers, grunts and jacks being targeted by the local fishermen. Lobsters and conch are also very valuable fishery resources, but information is insufficient for effective management. More research and monitoring on the trends in fishing activities in the MBRS region are required.

Acknowledgements

SMP is carried out with all staff on the MPAs included. We would like to thank them and park managers, captains, park rangers, officers and volunteers that have made possible the implementation of the program in each country. We would like to give a special recognition to: Adrián Oviedo, Calina Zepeda, David Jaén, Felipe Fonseca, James Azueta, Juan Chub, Kirah Forman, Marinés Millet, Miguel Alamilla, Rafael Roldan and Sheryl Shea for their contributions to this report. We also would like to thank to ICRI scholarship to support two of the authors to attend to the 11th ICRS.

Abstract. Coral reefs are sites of high nitrogen fixation activity where marine cyanobacteria are the major contributors. In coral reefs cyanobacteria can be found in very diverse environments: water column, sandy bottoms, on coral rubbles as endolithic and epilithic forms, or forming microbial mats. The purpose of the present research is to evaluate N_2 fixation rates in different environments (sandy bottom, coral rubble and cyanobacteria mats) and their contribution to the net primary production. Two different fringing coral reef sites were studied: Sesoko at Okinawa, Japan and La Reunion at the Indian Ocean. N_2 fixation and primary production rates were measured using ^{13}C and ^{15}N fixation techniques. Daily N_2 fixation in sandy bottom was about 3 nanomoles N/µg Chl-*a*, with near 6% contribution to the primary production. In coral rubbles it ranged from 0.5 to 7 nanomoles N/µg Chl-*a* with 2.4 to 28% contribution to primary production, while in cyanobacteria mats it varied between 0.2 to 242 nanomoles N/µg Chl-*a* with contributions of 2.8 to 42% to the primary production. Differences in N_2 fixation rates between daytime and nighttime indicated the presence of both heterocystous possessing and non-heterocystous possessing cyanobacteria.

Key words: N_2 fixation, Cyanobacteria, Endolithic algae.

Introduction

Biological nitrogen fixation is a process unique to prokaryotes, occurring commonly in freshwater and marine cyanobacteria. Although energetically demanding, this process provides the organisms with a particular advantage when growing under N-limited conditions, which are most frequent in marine environments (Staal et al. 2001). Due to oxygen sensitivity of the nitrogenase enzyme, the fixation of carbon and nitrogen in an oxygen-producing organism needs to be separated either in space or in time (Berman-Frank et al. 2003). Spatial separation is achieved in heterocystous cyanobacteria which are able to fix nitrogen during the day, contemporaneous with their energy generation. Non-heterocystous cyanobacteria temporally separate nitrogen fixation and oxygenic photosynthesis by fixing nitrogen at night, using photosynthetic energy generated during the previous day (Lundgren et al. 2003). Biological nitrogen fixation appears to make a major contribution to N supply in coral reef ecosystems, as has been shown for the Eniwetok Atoll (Webb et al. 1975), the Great Barrier Reef (Larkum et al. 1988), and for the lagoons of Tikehau Atoll (Charpy-Roubaud et al. 2001) and New Caledonia (Charpy et al. 2007). Many studies on N_2 fixation have dealt with shallow coral reefs (Larkum et al. 1988; Shashar et al. 1994, Charpy-Roubaud and Larkum 2005), however they did not identified N_2 fixers in coral rubbles. In the present study, we measured ^{15}N and ^{13}C uptake in benthic cyanobacterial populations associated to coral rubbles as endolithic or epilithic forms, in sandy bottoms, and forming microbial mats in shallow coral reef lagoons at St. Gilles (La Reunion Island, Western Indian Ocean) and Sesoko (Okinawa Island, Japan).

The objectives were to identify *in situ* dominant nitrogen fixers among benthic cyanobacteria, to measure their nitrogen fixation rates and the percentage of new production achieved throughout the N_2 fixation. Moreover we compared the results obtained from two geographically remote sites of Indian Ocean and Pacific Ocean respectively.

Material and Methods

The present study is based on the field research carried out at La Reunion Island in November, 2004 and in February, 2007 and at Sesoko Island of Okinawa in July, 2005 and October, 2006. La Reunion Island is located in the South-Western Indian Ocean (21°7'S, 55°32'E), 700 km east of Madagascar.

The common reef geomorphology includes an outer slope, outer and inner reef flats and a back reef. The fringing reefs are discontinuous and narrow covering only 7.3 km^2. The reef flats are exposed at low tide. The studied area was located at La Saline along the southwestern coast of Reunion Island. The depth of the study area never exceeded 2m. Live coral coverage varied between 20 and 30% and macroalgal cover reached 40% on the reef flat. Sesoko Island (26°38'N, 27°51'E) is located off the NW coast of Okinawa in the Ryukyu Archipelago, South-Western Japan. The sea around the Ryukyus is under the influence of the warm Kuroshio Current and characterized by the development of coral reefs from latitudes 24° to 31°N, marking their northernmost distribution. Two sampling stations were selected in July, 2005 and October 2006, Station B (1 to 2m depth) located in a moat on the west coast of Sesoko Island behind a well-developed reef crest, located 150–200 m from the shore, and Station C (2 to 3m depth) located next to the pier of Sesoko Station, Tropical Biosphere Research Center of the University of the Ryukyus. Reefs around Sesoko Island are actually in a post bleaching phase with less than 10% of living coral coverage, 50% of sandy bottom, 30% of coral rubbles and the rest covered by macroalgae and turf algae (Casareto, unpublished data).

Temperature and light were monitored over the duration of the surveys using in situ sensors (MDS-MkV/T and MDS-MkV/L, Alec electronics). Salinity and nutrient concentrations were routinely measured during field studies. Triplicate sub-samples of sea water for nutrient measurement were collected into clean acid-washed 100 ml polyethylene bottles and kept frozen. Nutrients were determined with an autoanalyzer (TRAACS-2000: BRAN+LUBE) according to Hansen and Koroleff (1999). Nitrate was determined by subtracting the values of nitrite from nitrate + nitrite. The detection limits were 0.052 µM for NO_3 + NO_2, 0.01 µM for NO_2, 0.020 µM for NH_4 and 0.020 µM for PO_4. Reproducibility of nutrient analysis was ± 0.5% .

Sampling of coral rubbles, sand and cyanobacteria mats were done using snorkeling or scuba diving, and documented by underwater photography. Samples were gentle placed into sterilized tubes or plastic bags, kept in cool box and brought back to the laboratory for sub-sampling and treatments. In the laboratory aliquots of the materials were placed in small flasks and kept with formaldehyde (4%) for later microscopic analysis and taxonomic identification. Other aliquots were used in incubation experiments for N_2 fixation and primary production measurements. For coral rubbles, two small branches of similar size were placed into the incubation bottle which was filled with seawater collected simultaneously at the same sampling point (incubation of epilithic plus endolithic algae). Other two branches of similar size were previously gentle brushed to remove the epilithic community and place in another incubation bottle also filled with seawater of the sampling point (incubation of endolithic algae). Aliquots of 10g of sand were placed into the incubation bottles which were filled with seawater from the same sampling point. Aliquots of approximately $1cm^2$ of cyanobacteria mats were placed into the incubation bottles and filled with seawater from the same sampling point. Control incubations using only seawater from the sampling points were carried out. All incubation bottles were enriched with ^{15}N and ^{13}C, and incubated *in situ*. Incubation started before the sunset and continued until early morning (12h incubations) for N_2 fixation of non-heterocystous cyanobacteria. For heterocystous cyanobacteria the incubation continued until the end of the following day (Charpy et al. 2007).

N_2 fixation rate and dissolved inorganic carbon uptake measurements were carried out according to Slawyk et al. (1977): Samples placed into polycarbonateincubation bottles of 180 mL fitted with a septum, were enriched with 0.36 mL of ^{13}C-labelled sodium bicarbonate ($NaH^{13}CO_3$ – 100mg in 10 mL of deionized water – 99.9% ^{13}C) to obtain an enrichment of 11.5%. Subsequently, 0.36 mL of $^{15}N_2$ (99.8 atom %, Shoko Co. Ltd, Tokyo, JAPAN) was added with a gas-tight syringe to obtain an enrichment of 6.8%. For mats, incubations were terminated by filtration under gentle pressure through a precombusted 47-mm diameter GF/F filter, acidified by HCl fumes and dried. For coral rubbles and sand, small subsamples were mashed on mortars and treated with HCl to remove the carbonates, and posterior filtrated onto precombusted 47-mm diameter GF/F filter. Filters were dried on 60°C for POC, PON, and isotope analysis. Similar subsamples without acidification treatment were prepared for HPLC analysis. Measurements of delta ^{13}C, delta ^{15}N, and POC, PON were done using a mass spectrometer DELTA plus Advantage (Thermofinigan Co.) equipped with EA1110 for measurements of POC and PON. Primary production was calculated according to Hama et al. (1993) and N_2 fixation rate was calculated by isotope mass balance as described in Montoya et al. (1996). Chlorophyll (Chl-*a*) analyses were performed by spectrophotometry for La Reunion 2007 samples and by HPLC for La Reunion 2004 and Sesoko samples. Chlorophyll for spectrophotometric analysis was extracted in 10 ml of 100% methanol, and optical density at 665 nm was recorded before and after acidification. Chl-*a* concentration was calculated using the extinction coefficients given by Porra et al. (1989). For HPLC analysis, the pigments were

extracted with 95% ethanol. HPLC was carried out with a model LC-10AT$_{VP}$ (Shimadzu, Kyoto, Japan). Pigments were eluted at a flow rate of 1.0 mL/min at 25°C with a programmed binary gradient elution system. Separated pigments were detected spectrophotometrically with a photodiode array detector (Shimadzu SPD-M10AVP), measuring from 400 to 760 nm.

Results and discussion

Environmental parameters

Temperature, salinity and nutrient concentrations in the ambient water of studied sites at La Reunion and Sesoko islands are summarized in Table 1. The total dissolved inorganic nitrogen (DIN) was highest in La Reunion in November 2004 (1.71 µM) and lowest in Sesoko in Station B in October 2006 (0.20 µM). In La Reunion, high values of ammonia and nitrate indicate some degree of eutrophication and coastal pollution. Reduced nitrogen compounds were always low in Sesoko. Dissolved PO_4 concentrations were low (<0.21 µM) in all stations during all the study period. Water temperature and salinity in both sites were comparable during the study period and so was the photon flux.

Taxonomy

Algae associated to coral rubbles were studied microscopically after gentle brushing of rubbles previously fixed using formaldehyde. For the endolithes gentle acidification treatment was done. Algae associated with sand or cyanobacteria forming mats were studied under microscope from formaldehyde fixed samples. The epilithic algae were composed by a wide spectrum of algae including chlorophytes, phaeophytes, rhodophytes and bacillariophytes. Cyanobacteria of the genus *Lyngbya, Oscillatoria* and *Phormidium* were the main as epilithic in La Reunion and *Calothrix, Gardnerula* (both possessing heterocysts), *Hydrocoleum* and *Lyngbya* in Sesoko. Endolithic algae were composed by chlorophytes (mainly *Gomontia* and *Ostreobium*) and *Hyella* (cf.) *caespitosa*, *Plectonema* (cf.) *terabrans*, *Mastigocoleus testarumin* and *Scytonema* (cf.) *conchophillum* (the last two species with heterocysts). Same species of cyanobacteria and a high diversity of epilithic diatoms were found in sandy bottoms at both sites. Among the cyanobacterial mats the main identified species in La Reunion were *Nodularia* (with heterocysts*)*, *Oscillatoria* and *Leptolyngbya* at La Reunion and *Hydrocoleum coccineum*, *Nodularia harveyana* (with heterocysts) and *Phormidium laysanense* at Sesoko.

N_2 fixation rates in coral rubble

N_2 fixation rates in coral rubbles from La Reunion and Sesoko at different studied seasons are shown in Table 2. At La Reunion, rates for the incubations with only the endolithic alga during the first 12h (dark period) varied between 0.4 to 0.9 nanomoles N per µg Chl-*a*, and were 2.8 to 6.8 nanomoles N per µg Chl-*a* during 24h incubation. This shows that N_2 fixation was performed mainly during the 12h light period, indicating that heterocysts possessing cyanobacteria were the main components of endolithic algae. N_2 fixation rates for rubble incubations with endolithic plus epilithic algae varied from 0.33 to 2.7 nanomoles N per µg Chl-*a* during 12h (dark) and 0.45 to 4 N per µg Chl-*a* during 24h of incubations. These results show that the contribution of epilithic algae to the total N_2 fixation in rubbles is not so important if compared with rates obtained for only endolithes. Moreover in November 2004 N_2 fixation rate during 24h for endolithic plus epilithic algae was lower than that during 12h dark period, indicating that during day time there is a loose of N_2 fixed during the night. For the overall data of coral rubble in La Reunion Island it seems that N_2 fixation raters are higher in February (summer) than that of November (dry season). At Sesoko, N_2 fixation rates of endolithic alga during the first 12h (dark) incubations varied between 0.6 to 3.6 nanomoles N per µg Chl-*a* and 1.4 to 7.2 nanomoles N per µg Chl-*a* during 24h. Higher values of N_2 fixation during 24h incubations indicate that during light period N_2 was fixed and therefore this shows the presence of heterocyst possessing cyanobacteria. Rates for incubation with endolithic plus epilithic varied from 1.9 to 5.5 nanomoles N per µg Chl-*a* during the 12h dark period and 0.8 to 1.4 nanomoles N per µg Chl-*a* during 24h. These results show that in incubations with both epilithic plus endolithic algae fixed N_2 during the night was lost during the light period. For the overall data at Sesoko it seems that N_2 fixation rates by coral rubbles are higher in October (post summer season) than that of May (spring).

N_2 fixation rates of cyanobacteria mats

N_2 fixation rates of cyanobacrteria mats are shown in Table 3. Among the three species of cyanobacteria forming mats *Nodularia* showed high fixation rates (112 nanonoles N per µg Chl-*a*) during 24 hours compared with rates at dark period indicating the efficiency of the heterocyst possessing cyanobacteria. The other two identified species forming mats, *Oscillatoria* and *Leptolyngbia* showed almost no N_2 fixation activity during the day time. In Sesoko *Hydrocoleum coccineum* showed the higher rates of N_2 among all the studied cyanobacterial mats, being 288 nanomoles N per µg Chl-*a* during the night and 242 nanomoles N per µg Chl-*a* during 24h.While these species do not posses heterocysts and the N_2 fixation activity was observed mainly during the night period, these rates were one order of magnitude higher if compared with other mats from Sesoko or two times to two orders of magnitude higher when compare with fixation rates of mats at La Reunion Island

N_2 fixation rates of sandy bottom

N_2 fixation measurements of sand were performed only at Sesoko Island. Rates are shown in Table 4. During the dark period, rates were 0.35 nanomoles N per µg Chl-*a* and 2.8 nanomoles N per µg Chl-*a* in 24 h. These rates are comparable to the lower rates observed for coral rubbles at La Reunion during November.

Site and 0rganism	Primary Production (nmoles C µg Chl-a^{-1}day^{-1})	N_2 fixation 12h (dark) (nmoles N µg Chl-a^{-1}day^{-1})	N_2 fixation 24h (nmoles N µg Chl-a^{-1}day^{-1})	C/N	Organic carbon production by N_2 fixation (nmoles C µg Chl-a^{-1} day^{-1})	Contribution of N_2 fixation to Primary Production (%)
Sesoko Sandy bottom	545.4 ± 118.2	0.35 ± 0.3	2.85 ± 2.0	10.9 ± 1.6	31.6 ± 25.2	5.7 ± 3.9 n = 6

Contribution of N_2 fixation to primary production:
On the bases of measured C/N ratios of all the studies substrata (see tables 2, 3 and 4) it is possible to calculate the amount of organic carbon which can be fixed as new production on the bases of the fixed atmospheric nitrogen. Further, using the measured primary production rates, it is possible to estimate the contribution of new production to the total primary production of the studied substrata. For coral rubble from La Reunion this contribution varied from 24% to 28% for endolithic algae and from 2.4% to 17% for epilithic plus endolithic algae. At Sesoko the contribution of N_2 fixation to primary production of coral rubbles was lower and varied between 3.5% to 17% for endolithic algae and 4% to 10% in case of epilithic plus endolithic algae. In case of cyanobacteria mats, the contribution of N_2 fixation to the total primary production varied from 2.8% to 42% at La Reunion and from 12 to 28.5 at Sesoko. In sandy bottom, the contribution of new production to the total primary production was 5.7%

Table 5. N_2 fixation rates during night and 24h of coral rubble, cyanobacteria mats and sandy bottom in comparable units of mg N m^{-2} $time^{-1}$

Type of Sediment	Location	N_2 fixation 12h (dark) mg N m^{-2} $time^{-1}$	N_2 fixation 24h mg N m^{-2} $time^{-1}$
Coral gravel	Sesoko	1.45 ± 0.84	2.37 ± 1.93
	La Reunion	0.57 ± 0.37	2.07 ± 1.2
Cyanobacteria mat	Sesoko	64.14 ± 3.05	94.81 ± 7.42
	La Reunion	27.12 ± 7.32	96.98 ± 2.28
Sand	Sesoko	0.20 ± 0.17	3.08 ± 1.79

Conclusions
Biological N_2 fixation was found in all the studied substrata. The presence of heterocysts possessing cyanobacteria was important among the endolithic algae and showed higher efficiencies of N_2 fixation and important contribution to primary production (up to 28%). Highest N_2 fixation was observed in cyanobacterial mats. In particular *Hydrocoleum coccineum* (Sesoko) was the highest among the non-heterocysts cyanobacteria and *Nodularia* (La Reunion) among heterocysts possessing ones. The contribution to primary production was up to 34%. In sandy bottom N_2 fixation rates was similar to that of coral gravel at the same location and season (Sesoko, May), but this fixation represented less than 6% of required N for the primary production.

Table 5 shows a summary of the results of N_2 fixation rates for the three studies substrata in terms of mg of fixed N_2 per m^2. These results show that N_2 fixation rates of cyanobacteria mats are order of magnitude higher than that of coral rubbles or sandy bottom. However, considering the covered area in the whole reef, the contribution of coral gravel and sandy bottom might be the highest. In the present study all cyanobacteria mats were found to be of small size and covered less than 1% of the total reef area.

Abstract. Coral Reefs are declining worldwide due to bleaching and diseases. Biogeochemical role and mechanisms of behavior of dissolved organic matter remain unexplained on this context. Here we discuss the changes of dissolved organic nitrogen by composition of amino acids as a model study, to demonstrate linkage of coral stress to elevated temperature and behavior of chemical substances in the coral biological system. Results suggest that high concentrations of nutrients and organic matters are due to the materials release by coral organism under the elevation of water temperature. This indicates observed organic nitrogen such as amino acids, peptides, proteins released as response to coral thermal stress. C: N and N: P ratio of coral mucus of thermal stressed and initial shows that thermal stress increases production of organic nitrogen and connected to increase of total amino acid could be peptides or proteins. This is shown by total hydrolyzed amino acids released from coral under the heat stress contains mix of peptides or proteins. However, to determine and confirmed source of organic nitrogen within this context need further experiments integrating microbial sources and processes. We propose to include chemical perspective in the coral biological system by the concept of chemical symbiosis.

Key words: TOC, TON, TOP, Amino Acids, Coral Reefs, Chemical symbiosis.

Introduction

Coral reefs are declining at alarming rate worldwide, bleaching and immerging diseases are recorded for the degradation of coral reefs. Coral bleaching damages of the symbiotic zooxanthellae are presently believed to result largely from elevated temperature of the seawater and the increase of UV radiation (Hoegh-Guldberg 1999, Glynn and Crox 1990, Jokiel and Brown 2004). Mild or moderate bleaching is commonly followed by recovery, but the long-term effects of high temperature of seawater will end in an irreversible bleaching and massive death of corals. As an adverse effect of rising up seawater temperature, coral animal undergo stress, response to this stress, corals release high amounts of organic matters as mucus and ammonia (Krupp 1984). The composition of coral mucus contains variable of macromolecular compounds (Ducklow and Mitchell 1979). This suggests that organic matters in dissolved (DOM) and particulate (POM) forms might play an important role for the fate of corals and coral ecosystem (Suzuki et al. 2000 and Casareto et al. 2000) especially for the resistance of coral under the heat stress. The production of organic matters by corals can act as a mechanism for defense but also it is used in feeding for particles capture strategy. High amount of ammonia in the reefs surrounding waters can enhance the growth of pico-phytoplankton (Casareto et al. 2004, Charpy 2004), which acts as main food source for benthic community. However organic matters may enhance the growth of certain bacteria, which are known to infect corals and induce bleaching and diseases (Kline et al. 2006). Therefore release of organic matter play an important role in biogeochemical cycles of coral reef ecosystem. The knowledge from this prospective is needed further to explain the sources and utilization of organic matter cycling in coral reefs to describe coral stress and health. Dissolved organic nitrogen (DON) is that subset of the dissolved organic matter (DOM) that contains nitrogen. Large part of nitrogen compounds in coral reef waters are found as DON, while inorganic nitrogen concentration is very less in coral reef waters, because coral reef is located in the oligotrophic area. But this is "paradox" for understanding of high productivity and bio-diversity of coral reef. Most of DON is consisted of peptide, protein, amino acids, urea, etc, behavior of these

compounds can influenced by coral stress due to sea temperature rise explained in global warming. DON is a heterogeneous mixture of compounds with various time scales from days to hundred years as refractory substances. A large number of compounds have been identified within the DON pool, including dissolved combined amino acids (DCAA) and dissolved free amino acids (DFAA). When stress has been given coral by increasing water temperature, light intensity and others, coral releases mucus as defense against invasion by bacteria and/or virus. It is well known that most of mucus is accepted as carbohydrate and lipid which are DOC, and less protein (Coffroth 1990). However there are very few reports on the DON and protein in mucus. Here we report the behavior of dissolved organic nitrogen and amino acids concentration; distribution and changes in its characteristics (composition of amino acids and molecular weight) elevated water temperature from field and incubation experiments with suggestions link the coral stress and chemical behavior of substances within coral biological system and reef as a whole.

Material and Methods

Experiments of heat stress: Experiments were done at the Sesoko Laboratory of Tropical Biosphere Research Center, Ryukyu University, Okinawa, 2006 Japan Fixed 10 branches of *Montipora digitata* specimen collected around Sesoko Island in 400 ml tank. Tanks were filled with filtration water with double filters of GFF and water was circulated with 20 ml $min.^{-1}$ from tank with 100 L to the same tank. All experimental vessels were kept under the water bath with 28^0 and 35^0, respectively. Light intensity was adjusted to 400uM with switch on and off in 12hours interval.

Measurements: Mucus samples for measurements were taken at every day during the times as 5:00, 9:00, 16:00, 23:00, for measurement for TON (total organic nitrogen) and TOP (total organic phosphorus) using an Auto-Analyzer (Braun-Lube) after digestion with alkaline persulfate, nutrients (nitrate, nitrite, ammonia, phosphate) using an Auto-Analyzer (Braun-Lube), amino acids using HPLC(Agilent) and Total Organic Carbon (TOC) by TOC 5000 (Shimadsu).

Results

Variation of inorganic nutrient concentrations recorded for temperature 28^0C and 35 ^{0}C during the experiment (Fig. 1). Also variations of Total Organic Nitrogen (TON) and Total Organic Phosphate (TOP) Concentrations are shown (Fig.2). High concentrations of ammonia, phosphate, TON and TOP were found significantly in samples of 35^0C at 9:00 a.m. of 27, July (Fig.2) Ammonia concentration increased to 3.6μM from 0.04μM with a couple of 100 times. Organic matters concentrations also increased to 29.9μM from3.3μM for TON with 10times and to 0.22μM from0.03μM for TOP.

Discussion

This experiment demonstrates new information on DON not previously reported and point's importance of linkage between coral stresses under the elevated water temperature for release of chemical substances. Results also suggest that high concentrations of nutrients and organic matters are originated by coral stress as elevation of water temperature. This indicates that organic nitrogen such as amino acids, peptides, proteins released as stress response. Considering stressed condition C: N ratio with 7 is lower and N: P ratio with 150 is higher compared with the initial samples. This observation argues that higher organic nitrogen corresponds to increase of total amino acid may be representative of peptides and proteins. Also the THAA released from coral under the heat stress supports that this possibly be peptides and or proteins. This demonstrates the considerable increment of the concentration of Proline in higher temperature could be a good representative for coral heat stress within the DON pool. However, for determination the source of organic nitrogen required further more research including microbial component. We also observed increment of bacterial abundance (Unpublished data Casareto and Suzuki), bacteria cell wall contain peptidoglycan as membrane and proteins. Future experiments will be more comprehensive after including Chemical exchange within water column, microbial component and coral biological system. We propose to include more chemical perspective in the coral biological system find the dynamics of chemical cycling by introducing the concept of chemical symbiosis within the coral animal. A simple schematic diagram in Fig. 4 explains the basic concept of chemical Symbiosis.

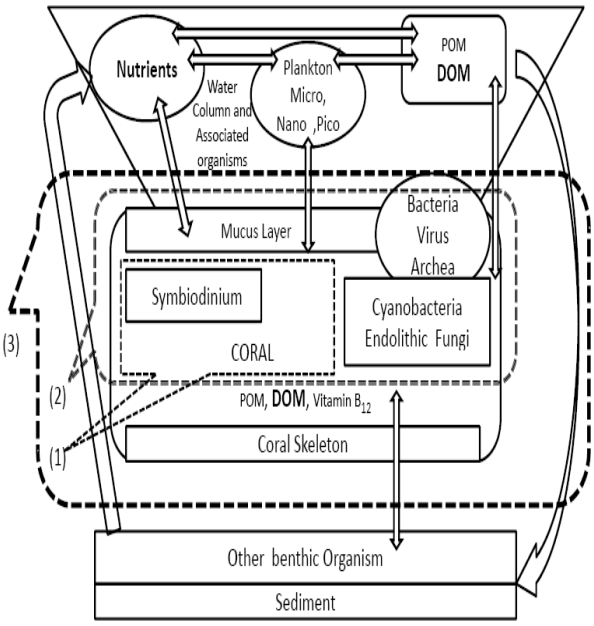

Figure 4: Proposed conceptual illustration for the chemical symbiosis with connection to detection of environment stress and physiological change in coral biological system in chemical prospective. Highlighted words reflect results to this paper. The cages represent concepts of (1) biological symbiosis, (2) holobiont and (3) chemical symbiosis.

Coral Symbiosis is well explained in coral biology and widely used in literature to show the coral animal and zoxanthellae relationship in hermatypic corals (Muscatine et al. 1984) and in microbial prospective coral system also explained as coral holobiont (Rohwer et al., 2002). However there are similarities and some differences with our proposed chemical symbiosis concept based on presentation of the idea from different perspective. Proposed concept for chemical symbiosis describes the exchange of

chemical substances such as organic material, nutrients and vitamin B_{12} (Agostini et al., unpublished) essentials for the living coral biological system and production of non living organic matrix represent as coral skeleton. Also the concept of chemical symbiosis attempt to describe environmental stress and its physiological response in the view point of exchange chemicals and this chemical signals can represents the physiological indicator either in environment or in coral organism. This is needed to reveal new insight of coral reef biogeochemical cycles.

Abstract. Sedimentation is a major source of disturbance to coral reefs. However, the documentation of healthy coral communities in areas with high sediment and nutrient inputs suggests that an enhanced heterotrophic environment may allow corals to thrive under marginal conditions. Here, we document the effects of sedimentation on the survivorship and growth of *Porites astreoides* and *Siderastrea siderea* to evaluate whether the higher nutrient content of enriched sediments can be utilized to offset the negative impacts of sedimentation.

P. astreoides and *S. siderea* showed high tolerance to chronic sedimentation that reduced light levels and covered corals daily for three weeks. Limited tissue losses were observed, but total mortality was not recorded. Coral growth was significantly influenced by the addition of sediments. For *P. astreoides*, control corals had the fastest growth rates, followed by corals from the enriched nutrient treatment, non-enriched sediment treatment, and the shading treatment. For *S. siderea*, growth rates were highest for control corals, followed by corals in the enriched sediments treatment, the shading treatment, and the non-enriched sediment treatment. The enhanced growth of *Porites astreoides* and *Siderastrea siderea* exposed to nutrient-enriched sediments shows that corals are able to offset the negative impacts of sedimentation by assimilating sediment nutrients.

Key words: Sedimentation, coral growth, nutrient assimilation

Introduction

The impacts of sedimentation are regarded as an increasing threat to coral reefs worldwide (Bryant et al. 1998; McCulloch et al. 2003; Fabricius 2005). Rapid population growth, changes in land-use patterns, and watershed modifications have all increased terrestrial runoff to coastal habitats (Devlin and Brodie 2005). Moreover, urban development and activities such as beach nourishment and dredging have also resulted in increased sedimentation patterns on nearshore coral reef habitats with significant detrimental effects on coral abundance, diversity, and distribution (Wilkinson 2004; Fabricius 2005).

Most sedimentation-related research on coral reefs has focused on direct and indirect stress pathways that include reduced light, abrasion, smothering, burial, toxicity (Fabricius 2005; Sanders and Baron-Szabo 2005), and associated impacts that include reduced photosynthesis (Riegl and Branch 1995; Phillips and Fabricius 2003), partial or complete tissue mortality (Rogers 1983; Nugues and Roberts 2003), reduced growth (Rice and Hunter 1992), and reduced fertilization, larval survivorship, and recruitment (Gilmour 1999; Babcock and Smith 2000). However, recent studies indicate that reef habitats exposed to sedimentation, suspended particulate matter, and nutrient inputs have access to an enhanced heterotrophic environment that may allow corals to survive and thrive under conditions often considered as marginal for coral growth and reef development (Anthony 1999, 2000, 2006; Anthony and Fabricius 2000). Increased availability of heterotrophic energy and nutrient sources in nearshore coastal habitats has been linked to higher coral growth rates (Edinger et al. 2000), increased energy storage (Anthony 2006), and increased resilience to disturbance (Grottoli et al. 2006).

The role of sediments as a potential source of nutrition for corals has been documented in studies that showed that organic matter from sediments can be transferred to the coral tissue (Rosenfeld et al. 1999), and that corals can selectively extract food particles from sediments (Mills and Sebens 1997) and assimilate the N available in sediments (Mills and Sebens 2004). In this study, we document experimentally the effects of high sedimentation on the short-term (i.e., 3 weeks) growth of two Caribbean coral species, *Porites astreoides* and

Siderastrea siderea, and evaluate whether the higher nutrient content of enriched sediments can be utilized by corals to offset the negative impacts of sedimentation.

Methods

Porites astreoides and *Siderastrea siderea* are among the most abundant species in both inshore and offshore reefs of the Florida Reef Tract (Lirman and Fong 2007) and are commonly found in areas with high sedimentation (Rogers 1990). Fragments (2-3 cm in diameter) of *P. astreoides* and *S. siderea* were extracted from a single colony of each species, thus ensuring genetic uniformity of fragments. The coral colonies were collected from a mid-channel patch reef in the northern section of the Florida Reef Tract. Mean water nutrient levels for the area where the colonies were collected were 0.6 μM DIN and 0.03 μM SRP (Lirman and Fong 2007). Nutrient levels in the seawater used in this study had higher DIN (2.1 μM) and similar levels of SRP (0.04 μM; data provided by the NOAA/AOML/South Florida Program.

The fragments were attached to the PVC platforms used to measure coral growth using underwater epoxy and, after an acclimation period of two months, were placed into the 5-L aquaria used as experimental units. Coral fragments were randomly assigned to the following treatments: (1) controls; (2) non-enriched sediments; (3) enriched sediments; and (4) shading. Replicates for each treatment were 9 fragments for *P. astreoides* and 4 fragments for *S. siderea*.

Air was supplied with air stones and seawater was added continuously at a turnover rate of approximately 6-8 times every 24 hr. A barrier constructed of plankton netting material was glued to the top of the aquaria to trap sediments as the water flowed out of the aquaria. Corals were kept in a aereated, flow-through system (as opposed to a static system) to ensure that any changes in pH, dissolved oxygen, carbonate chemistry, and water nutrients due to the addition of sediments would be transient, thus isolating the impacts of sedimentation and sediment nutrients from these other potentially confounding factors. Measurements of pH, dissolved oxygen, and salinity inside the experimental aquaria before and after the addition of sediments did not show any significant impacts of sediment addition on these parameters. However, water nutrient levels were not measured after sediment addition. While we believe that the use of a flow-through system limits the influence of nutrients transferred from the sediments to the water column as a factor in this study, the lack of nutrient readings precludes a full separation between the potential effects of sediment nutrients and elevated water nutrients.

Similarly, the seawater supplied was filtered using a set of 10 μm and 1 μm canister filters to minimize the amount of external particles available to the corals. The aquaria were placed within flow-through holding tanks for temperature control and light was supplied by compact fluorescent bulbs on a 12-hour light and dark cycle. The aquaria were cleaned and repositioned at random within the holding tanks once a week. The amount of light reduction caused by sedimentation was measured with a LiCor sensor placed inside an aquarium where levels of PAR were measured at 10 min-intervals after sediment addition.

The sediments used in this study were collected from the top layer (< 5 cm in depth) at a reef from Key Largo, Florida. Mean particle size, calculated with a Coulter Particle Size Analyzer, was 176 μm (S.D. = ± 34, n = 4 samples). The sediments were placed in two aerated 10-gal aquaria filled with seawater one week prior to the start of the experiment. Nutrients were added to one of the aquaria to create an enriched sediment treatment. NO_3 and PO_4 were added to the seawater to achieve enrichment levels of approximately 20 μM N and 2 μM P above ambient (Fong et al. 2003). At the end of the experiment, five samples were collected from the control and enriched sediments and the nutrient content of sediments was measured by the Nutrient Analytical Services Laboratory of the University of Maryland.

Each day, sediments were added to the experimental aquaria at a concentration of approximately 1000 mg DW L^{-1}. The mean sedimentation rate within aquaria was 53 mg DW cm^{-2} d^{-1} (S.D. = ± 17). These high concentrations were within the range of values reported to cause significant negative impacts on coral physiology and were similar to the sedimentation values obtained for Biscayne Bay, a coastal lagoon adjacent to the city of Miami (Rogers 1990; Lirman et al. 2003; Fabricius 2005; Weber et al. 2006). Finally, to evaluate the effects of light reduction on coral growth, corals were kept under shade-cloth that reduced available light levels by 62.5 % throughout the experiment.

Coral growth was measured using a Keyence© high accuracy CCD micrometer that measures the height profile of corals mounted on PVC platforms with micron-accuracy (Fig. 1). An aluminum pin cemented into each platform provides a standard against which coral height can be accurately measured. By measuring the height profile of each fragment repeatedly, linear extension rates can be determined as the difference in height between measurement intervals. Reported vertical linear extension rates are the average extension rate over the

entire surface of the colony. Differences in growth rates were compared among treatments using ANOVA.

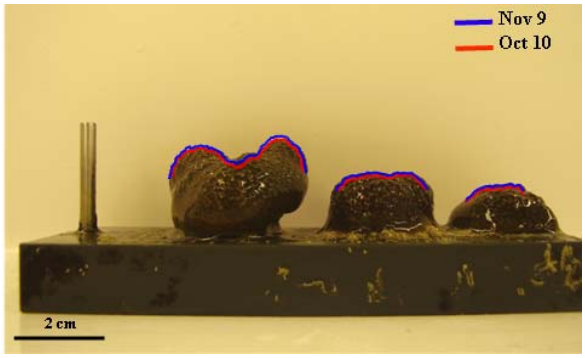

Figure 1: Photograph of the PVC platform used to measure vertical coral growth with a Keyence© high-accuracy CCD micrometer. Vertical growth along the coral contour was measured as the difference in height between intervals.

Results

Immediately after sediment addition, light levels inside aquaria were reduced to < 10 % of ambient levels but returned to pre-sedimentation levels (250 – 315 µE m^{-2} sec^{-1}) within 1.5 - 2 hr as the suspended sediments settled on the coral surface and the bottom of the aquaria. The light levels recorded after the sensor was completely covered by accumulated sediments were < 5 % of ambient levels. After addition, sediments were deposited rapidly over the coral surface and corals were covered completely within 45 min. The removal of sediments from the coral surface took up to 6 hr. Mean nutrient content was 10.3 µg g DW^{-1} (S.D. = ± 1.5) N and 2.1 µg g DW^{-1} (0.4) P for the control, non-enriched sediments, and 176.2 µg g DW^{-1} (± 62.2) N and 3.8 µg g DW^{-1} (0.4) P for the enriched sediments. The mean content of both N and P was significantly higher in the enriched sediments (t-test, $p < 0.05$). Total C (organic and inorganic) content (8 - 10 % DW) was not different between the sediment treatments (t-test, $p > 0.05$). The nutrient content of the sediments used in this experiment were similar to those values obtained from reef sediments in the Florida Reef Tract by Szmant and Forrester (1996). Enriched sediments used in this study had N values higher than those recorded for inshore reef habitats (25-140 µg g^{-1}) of the Florida Keys and P values within the range (2 -6 µg g^{-1}) observed for these habitats (Szmant 2002).

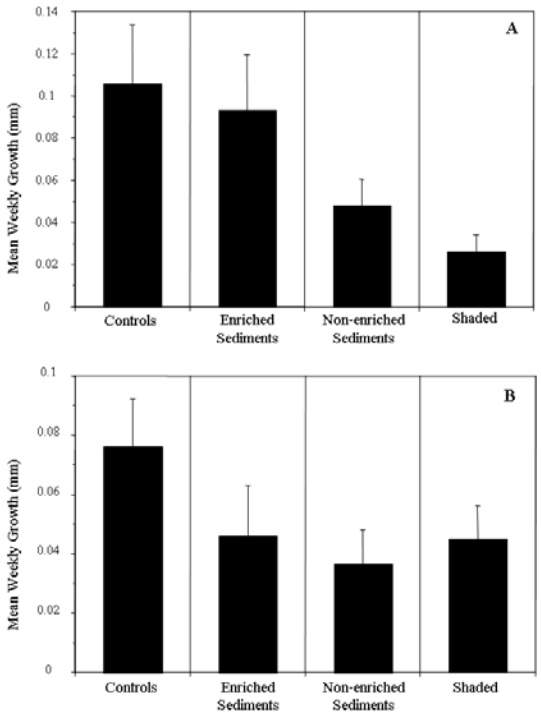

Figure 2: Growth of coral fragments of (A) *P. astreoides* and (B) *S. siderea* exposed to enriched sediments, non-enriched sediments, and shading treatments for a period of three weeks.

The growth of *P. astreoides* and *S. siderea* was significantly influenced by the addition of sediments. For *P. astreoides*, control corals had the fastest growth rates, followed by corals from the enriched nutrient treatment, non-enriched sediment treatment, and, finally, the shading treatment (Fig. 2A). No significant differences in growth rates were documented between control corals and corals exposed to enriched sediments. These two groups had growth rates significantly higher than those recorded for shaded corals and corals exposed to non-enriched sediments, which were not significantly different from each other (ANOVA, $p< 0.05$, Tukey HSD test).

For *S. siderea*, growth rates were highest for control corals, followed by corals in the enriched sediments treatment, the shading treatment, and the non-enriched sediment treatment (Fig. 2B). Significant differences were only documented between control corals and corals exposed to non-enriched sediments (ANOVA, $p < 0.05$, Tukey HSD test). Finally, some tissue losses were observed in the perimeter of the colonies, but none of the small fragments used in this study exhibited total mortality.

Discussion

Corals in marginal environments frequently encounter high levels of sedimentation and nutrients, and their

ability to maintain a positive energy balance and sustain growth under sub-optimal conditions are crucial to their persistence in these habitats (Anthony and Fabricius 2000; Lirman and Manzello 2009). The enhanced growth of *Porites astreoides* and *Siderastrea siderea* exposed to nutrient-enriched sediments shows that corals are able, at least in part, to offset the negative impacts of sedimentation by assimilating sediment nutrients. The ability of corals to assimilate nutrients and food particles contained in sediments has been previously documented by Rosenfeld et al. (1999) and Mills and Sebens (1997, 2004), but this is the first study to show a relationship between coral growth and the nutrient content of sediments. Future studies on the nutrient uptake of sediment nutrients by corals are needed to determine the nutrient pathways within the coral holobiont.

The response of corals to turbidity and sedimentation is influenced by species-specific light requirements and sediment rejection characteristics (Rogers 1983, 1990; Stafford-Smith 1993; Fabricius 2005). The present study showed a high tolerance of both *P. astreoides* and *S. siderea* to chronic high sedimentation levels that significantly reduced light levels and covered corals on a daily basis for three weeks. The ability to shed sediments and continue to grow under reduced light levels without significant tissue mortality correlates well with the high abundance of these two species throughout the Florida Reef Tract, even in areas with reduced water quality (Lirman and Fong 2007). Shading had the largest impact on the growth of *P. astreoides*, but the impact of light reduction in the absence of sediments was not significant for *S. siderea*. The green morph of *P. astreoides* used in this study is commonly found in shallow reef habitats (Gleason 1998) and may have a restricted depth distribution based on its higher light requirements.

In the Florida Reef Tract, a cross-shelf gradient in coral growth and mortality contrary to what was expected based on water quality patterns was documented by Lirman and Fong (2007). Corals from inshore habitats with higher nutrients and turbidity levels showed faster growth rates and lower rates of partial mortality compared to corals from similar habitats with lower nutrient and turbidity levels further away from shore. These findings led to the hypothesis that inshore habitats may provide an expanded heterotrophic niche for corals not available to offshore corals (Lirman and Fong 2007). This hypothesis is supported by research from Australia's GBR where corals in high-turbidity habitats are able to thrive due to particle feeding and nutrient assimilation (Anthony 1999, 2000, 2006; Anthony and Fabricius 2000). The higher growth rate of corals exposed to nutrient-enriched sediments compared to corals exposed to non-enriched sediments supports the hypothesis that the assimilation of nutrients from sediment sources may be partly responsible for the high growth rates documented for *P. astreoides* and *S. siderea* on inshore reefs where the highest levels of interstitial nutrients and N content of sediments are present (Szmant and Forrester 1996).

Finally, while enriched sediments can provide an additional source of nutrients for corals, sedimentation still remains one of the most significant sources of stress to corals worldwide. The balance between the negative impacts of sedimentation and the potential for enhanced heterotrophic sources of nutrition will depend on the frequency and intensity of sedimentation stress as well as species-specific tolerance patterns. Extensive research is still needed to fully understand the thresholds associated with sedimentation stress, but it is clear that prolonged exposure to sediments that exceed the shedding capability of corals can result in reduced growth, colony mortality, and significant modifications to coral abundance and community composition (Rogers 1990; Fabricius 2005; Dikou and van Woesik 2006). Moreover, while corals may be able to partly mitigate the cost of increased turbidity and the energy expended in clearing deposited sediments through nutrient assimilation, high organic and nutrient levels within fine sediments can cause tissue mortality through the increased activity of harmful microbial communities and the development of anoxic conditions (Weber et al. 2006).

Abstract. Corals continuously release mucoid organic exudates in order to clean their surfaces. Additionally, recent research highlighted the fact that this coral-derived organic matter acts as energy carrier and particle trap in the oligotrophic coral reef ecosystem, thus playing an important ecological role for recycling of matter and conservation of nutrients. Environmental stressors such as air exposure, high sediment loads and turbidity are known to increase the release of coral-derived organic matter. However although it is a common statement in the literature, scientific data verifying increased coral-derived organic matter release rates during temperature-induced bleaching events is lacking. This is critical as coral bleaching is the most extensive coral disease world-wide, and bleaching-induced changes in organic matter release potentially have far reaching consequences for reef functioning. In this study, a bleaching event was induced in the laboratory and release of dissolved and particulate organic carbon (DOC and POC) and nitrogen (PN) by the hermatypic coral *Acropora* spec. was quantified. Results show that during a bleaching event coral derived POC and PN release almost doubled compared to unstressed controls. This is the first experimental evidence that coral bleaching affects coral-derived organic matter release and potentially ensuing element cycles in tropical reef ecosystems.

Key Words: organic, matter, release, bleaching, stimulating

Introduction

Mucoid organic exudates continuously released by corals (Meikle et al. 1988) play an important role in heterotrophic feeding (Duerden 1906, Yonge 1930, Lewis and Price 1975, Lewis 1977, Sleigh et al. 1988, Goldberg 2002) as a defence against smothering by sediment (Schumacher 1977), desiccation (Daumas and Thomassin 1977, Krupp 1984), physical (Brown and Bythell 2005) and UVR related (Drollet et al. 1997) damage, pathogens (Ducklow and Mitchell 1979, Rublee et al. 1980, Cooney et al. 2002) or pollutants (Mitchell and Chet 1975, Neff and Anderson 1981, Bastidas and Garcia 2004). However, as mucoid organic exudates can dominate the suspended particulate matter (Johannes 1967, Marshall 1968) in reef waters, they are obviously also major components of the coral reef ecosystem's nutrient cycles. Wild et al. (2004a) suggested that these coral-derived mucoid exudates may function as energy carrier and particle trap, thereby helping to conserve essential nutrients in oligotrophic tropical coral reefs. Astonishingly, although the importance of coral-derived organic matter for reef ecosystem functioning is well documented, studies quantifying release rates in correlation to variations in the key environmental factors are rare.

During the last decades, the phenomenon of coral bleaching, i.e. the whitening of corals due to the loss of their symbiotic algae and/or pigments (Brown 1996), has become more and more evident all over the world. Mass coral bleaching events, triggered mainly by increases in water temperature, have affected the world's coral reefs with increasing frequency and intensity since the late 1970s (Hoegh-Guldberg 2004). It is predicted that due to a continued increase in seawater surface temperature (Bijlsma et al. 1995) from the year 2030 large scale bleaching events will occur annually (Coles and Brown 2003), leaving only a very short recovery period for the affected corals.

Despite the apparent actual threat of coral bleaching for the survival of coral reefs, no data is available concerning the associated release rates of coral-derived organic matter. However, such data is indispensable in order to allow any prediction concerning nutrient and energy budgets for future environmental scenarios in coral reefs. In this laboratory study, release rates of particulate organic carbon (POC), particulate nitrogen (PN) and dissolved organic carbon (DOC) by hermatypic corals of the genus *Acropora* during a temperature induced bleaching event were investigated.

In contrast to the methods of previous studies that have investigated release rates of organic matter in

relation to varying environmental factors excluding coral bleaching (Crossland 1987, Riegl and Branch 1995, Wild et al. 2005a), this study distinguished released coral-derived organic matter (mucoid exudates and host cells) from algal (zooxanthellae)-derived organic matter.

Material and Methods

Experimental description

All experiments were conducted in August and September 2007 in the aquarium facilities of the Department Biology II of LMU München, Germany. One coral colony of the genus *Acropora* was fragmented three weeks prior to the subsequent experiment in order to allow healing and regeneration. After the fragmentation, 10 coral fragments (surface Area: 72.4 - 126.2 cm²) were fixed on ceramic tiles (4.6 x 4.6 cm) using conventional coral glue. The experimental set-up consisted of two aquaria, the resident aquarium (215 L control aquarium), in which the fragments were maintained at non-heat-stress conditions, and a 30 L aquarium (bleaching aquarium), in which the temperature could be adjusted using a thermostat (HAAKE E52, Germany). The temperature in the resident aquarium was monitored by an ONSET underwater temperature logger revealing a temperature range between 25.6 °C and 29.3 °C in diurnal cycles. At the beginning of the incubation experiments, the coral fragments were placed in ten 1000 ml beakers filled with ca. 900 ml of filtered seawater (0.2 µm pore size) from the control aquarium. Manual transference into the beakers resulted in an expose to air of less than two seconds. Five beakers, each with one submersed colony (C1-C5), were placed in the control aquarium, thereby being exposed to the same temperature conditions as prior to the start of the experiment. The submersed fragments in the remaining five beakers were placed in the bleaching aquarium and acted as bleaching samples (B1-B5).

Initial water temperature for the bleaching samples was adjusted to 27 °C and kept at that temperature for 24 h, which complied with two incubation periods (one incubation period = 12 h). Introduction of compressed air ensured sufficient air supply and water circulation. After 12 h incubation, all coral colonies (B1-B5, C1-C5) were transferred to additional 1000 ml beakers filled with ca. 900 ml of freshly filtered seawater (0.2 µm). The incubation water of the precedent incubation period (IP) was kept for further processing as described below. This procedure was repeated every 12 h. After 24 h at 27 °C (IP 1 and 2), the temperature of the bleaching aquarium was raised every 12 h to a maximum of 32 °C at IP 7. Temperature was decreased to 29 °C and 27 °C for IP 8 and IP 9, respectively.

The occurrence of bleaching was defined as the point in time when zooxanthellae release rates of the bleaching samples were significantly higher than the release rates of the control samples. The surface areas of all coral fragments were measured as a reference parameter using the advanced geometry method described in Naumann et al. (submitted) and based on computer tomography reference as described by Laforsch et al. (2008).

Incubation water processing

The exact volume of the incubation water from all beakers was determined using a graduate 1000 ml glass cylinder with an accuracy of ± 20 ml. The incubation water was then stirred using a glass pipette and sub-samples (n = 1 for each parameter) were taken in order to determine the following parameters.

For subsequent **DOC measurements,** 5 ml of the incubation water were filtered through 0.2 µm syringe filters (FP 30/0.2 CA, Schleicher and Schell). The first 2 ml of the filtrate were discarded, but the following 3 ml were collected in precombusted brown glass bottles, which were instantly shock-frozen at -80 °C and kept frozen until analysis. For **POM quantification** (particulate organic matter), 50 ml of the incubation water were extracted and filtered by a vacuum filtration unit onto precombusted GF/F filters (Whatman, 25 mm diameter). Filters were dried for at least 48 h at 40 °C and kept dry until analysis. Another 50 ml were fixed with 2-3 drops of Lugol's solution and stored at room temperature for subsequent **enumeration of zooxanthellae** using counting towers and backlight microscopy at 400-times magnification (Axioplan, Zeiss Germany).

The remaining incubation water was fixed with formaldehyde (1 % formaldehyde end concentration) and stored in the dark at 4 °C until further treatment.

Organic matter analysis

POM analyses were conducted using an Elemental Analyzer NC 2500 for C- and N determinations (Carlo Erba, Italy). For calibration of the elemental content of the samples, two standards, Atropine ($C_{17}H_{23}NO_3$) and Cyclohexanone-2,4-dinitrophenylhydrazone ($C_{12}H_{14}N_4O_4$) were used. Obtained POC and PN values equal the total amount of released particulate organic matter (POMt). In order to obtain the released amounts of coral-derived particulate organic matter (POMc) the amount of released algal-derived organic matter (POMa) was subtracted from POMt**.** Consequently coral-derived organic matter is defined as any organic matter (mucoid exudates, host cells) released by the corals except algal cells.

For calculating the amount of released POMa, the POC and PN contents of a distinct number of

zooxanthellae was determined. Therefore a zooxanthellae suspension was produced by centrifugation (6000 g) of 400 ml incubation water from B2 after IP8. The pellet was resuspended in filtered seawater and the zooxanthellae concentration (9330 cells ml^{-1}) was determined (methodology see above). Dilution series of 0.1, 1.0, 10.0 and 50.0 ml of this solution were subsequently filtered in triplicates onto precombusted GF/F filters (Whatman). The filters were dried at 40 °C for at least 48 h before POM analysis as described above.

The released amounts of algal derived particulate organic matter (POMa) was determined by multiplying released numbers of zooxanthellae by the respective calculated carbon and nitrogen contents of a single *Symbiodinium* cell.

Bacteria abundances for 2 bleaching and 2 control samples were determined using standard DAPI coloration and fluorescence microscopy. Assuming a carbon content of 20 fg C per cell (Lee and Fuhrmann 1987), bacteria in the bleaching samples would account for 3.1 to 5.2 % of the total recorded C content. In the control samples, bacteria would account for 4.0 to 6.0 % respectively. In the light of these calculations microbial contribution was considered minor.

Unfortunately, bleaching samples B1, B4 and B5 showed necrosis after IP 7 (12 h at 32 °C). The incubation water of these fragments was therefore excluded from all further analyses unless otherwise stated.

DOC concentrations were determined by high temperature catalytic combustion (HTCO) using a Rosemount Dohrmann DC-190 total organic carbon (TOC) analyser and Potassium hydrogenphtalat as standard solution. Each sample was acidified by adding 100 µl of 20 % phosphoric acid and purged for 5 min in order to remove inorganic carbon. The DOC concentrations of each sample were measured five times. An outlier test was conducted, and the DOC concentrations of the remaining sub-samples were averaged.

Results

Induction of a bleaching event

A bleaching event was induced in the laboratory by exposing the investigated coral fragments to temperatures increased by 3 to 5 °C (Fig. 1a). Zooxanthellae enumeration revealed that from the IP 5 (30 °C) to the IP 9 (27 °C) significantly more (Table 1) zooxanthellae were released by the coral fragments incubated under elevated temperature compared to the controls (Fig. 1a).

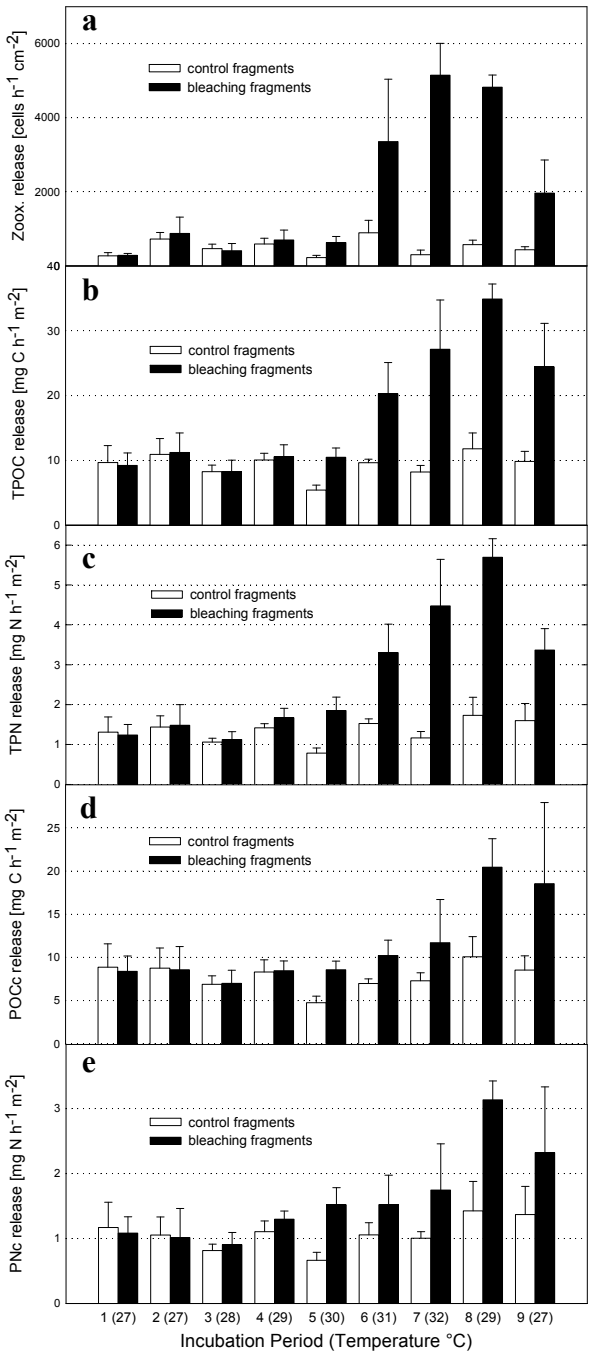

Figure 1: Summary of organic matter release rates during artificial bleaching experiment a) zooxanthellae release b) total POC release c) total PN release d) coral-derived POC release e) coral derived PN release.

Release of POCt and PNt

Throughout non-bleaching conditions there was no significant difference between the controls and the bleaching samples (Fig. 1b,c). Under bleaching conditions, from IP 5 (30 °C) until IP 9 (27 °C),

bleaching samples showed significantly (Table 1) higher POCt and PNt release rates. During IP 8 (29 °C), bleaching samples exhibited highest POCt and PNt release rates.

Regarding all bleaching samples (B1-B5), including those partially necrotic, POCt release rates were also highest during IP 8 (29 ° C) with release rates of 114 ± 75 mg C h^{-1} m^{-2} (mean ± SD, n = 5) and 14.0 ± 7.6 mg N h^{-1} m^{-2} (mean ± SD, n = 5).

Table 1: Summary of statistical analysis (independent samples t-test): given are p values for hypothesis for no differences between control fragments and bleaching fragments. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$

27 °C	**	**	**	**	**	*	0.115

Release of POMa and POMc

The released amounts of algal derived particulate organic matter (POMa) directly correlated with the zooxanthellae release rates, as POMa release was calculated by multiplying the released numbers of zooxanthellae with obtained POC and PN content of 0.3 and 0.05 ng $cell^{-1}$, respectively (linear regression of zooxanthellae numbers against respective POC content, $R^2 = 0.999$). Consequently, POCa and PNa release of the bleaching samples was significantly higher than that of the control samples whenever bleaching, as defined above, occurred (Table 1).

Algal-derived POC and PN release of the bleaching samples was lowest at IP 1 (27 °C) and highest during IP 7 (32 °C). The highest increase of algae-derived POC/PN release was found during IP 8 (32 °C), when bleaching samples released 11 to 35 times more algae-derived POC and PN than the control samples.

POMc was calculated subtracting POMa from POMt. Throughout non-bleaching conditions there was no significant difference between the treatments concerning POCc and PNc release (Fig. 1d,e). Coral-derived POC release accounted for 76 to 91 % of the total released POC and coral-derived PN for 68 to 88 % of total released PN under non-bleached conditions. Bleaching samples during IP 5 (30 °C) released significantly (Table 1) more POCc and PNc compared to the controls. During bleaching, coral derived POC release accounted for 42 to 82 % of released POCt and coral-derived PN accounted for 38 to 82 % of total released PN. Maximum POCc and PNc release could be detected during IP 8 (29 °C).

Release of DOC

No significant differences between bleaching and control samples concerning DOC concentrations could be found after any incubation period and treatment.

Discussion

Coral bleaching and organic matter release

Coral bleaching was induced at elevated temperatures (30 °C – 32 °C), but also occurred when temperature was decreased to 29 °C and 27 °C at the end of the experiment. This temporal delay may be explained by the effect of heat stress, which can lead to the breakdown of enzymatic pathways in plants and animals, resulting in metabolic or biochemical dysfunction (Cossins and Bowler 1987). Reinstalling these enzymatic pathways may take a few hours to days, depending on the damage evoked by heat stress. Thus, although temperatures were adjusted to non-bleaching conditions, the release rates were still elevated in the bleaching samples.

Besides the total release of POM, the exclusive release of particulate coral-derived organic matter was increased. This may be attributed to either increased release of mucoid exudates or increased release of coral cellular material as a consequence of the bleaching mechanism (e.g. host cell detachment). If the mechanism of bleaching, i.e. the release of zooxanthellae, was solely responsible for increased coral-derived organic matter release, the release of coral-derived organic matter should be highest when zooxanthellae release during bleaching was highest. However, coral-derived organic matter release was highest at 29 °C when zooxanthellae release had already decreased (Fig. 1a,d,e). Consequently, the mechanism of bleaching was very likely not the only factor responsible for increased coral-derived organic matter release. Therefore, increased release of mucoid exudates apparently co-occurred during bleaching.

The measured total organic matter release rates of the non-stressed control fragments are in the same range as release rates described in previous field studies (Table 2). Including coral fragments with partial necrosis, release rates were similar to those measured during air exposure (Table 2). As necrosis is one of five possible mechanisms resulting in expulsion of zooxanthellae (Gates et al. 1992), and commonly occurs during bleaching (Glynn et al. 1985), these findings underline the relevance of bleaching events for energy and nutrient cycles in the reef ecosystem. This is confirmed by the study of Wild et al. (2004b), who found that coral-derived organic matter is rapidly degraded by reef microbes, in contrast to zooxanthellae-derived organic matter, which may rather represent a loss of energy and nutrients for the reef ecosystem (Wild et al. 2005b).

Table 2: Summary of studies examining organic matter release rates by corals of the genus *Acropora*. In the present study 45 replicates are displayed, because 5 coral fragments were incubated at 9 different periods. (Note: Previous studies used old definition of mucus and did not distinguish between coral- and algal-derived organic matter).

This study also showed that DOC release was not influenced by coral bleaching. This is surprising as Wild et al. (2004a) demonstrated that between 56 and 80 % of coral mucus can dissolve in the surrounding seawater. However, it is very likely that a high proportion of the released DOC was re-consumed by the coral and associated bacteria (Sorokin 1973, Al-Moghrabi et al. 1993). This explanation is supported by the studies of Ferrier-Pages et al. (1998) and Naumann et al. (unpublished data), who found that it is generally difficult to detect any DOC release by corals in a closed system such as a beaker.

Furthermore, DOM polymers can spontaneously assemble to form polymer gels, thus entering the POM pool (Chin et al. 1998), which could have lead to a removal of surplus DOC from the incubation water.

Ecological implications

Increased coral-derived POM release during bleaching can probably be attributed to increased release of cellular matter and/or to increased release of mucoid exudates. Increased release of cellular matter during bleaching can be explained by the mechanism of bleaching, which may lead to loss of parts of or entire coral cells. However, the reason for increased release of mucoid exudates is harder to surmise. Up to 45 % of carbon fixed daily by the zooxanthellae can be released as organic matter by the host coral (Davies 1984, Crossland 1987, Bythell 1988, Edmunds and Davies 1989). A bleached coral is in a state of energy shortage as the algal symbionts, which are capable of providing the coral host with up to 100 % of its daily metabolic energy requirements (Muscatine et al. 1981), are lost. Thus, it is not surprising that coral bleaching can affect the release rates of organic matter.

However, there are some ecological advantages and disadvantages of up-regulation of mucoid organic matter release during coral bleaching. On one hand, energy loss via mucoid organic matter release may further reduce the ability of corals to cope with bleaching, whereas on the other hand mucoid exudates release may function for heterotrophic feeding (reviewed by Brown and Bythell 2005), which could partly compensate the missing autotrophic contribution to the coral's energy demand during bleaching. Further, increased mucoid exudates release during bleaching may also help to protect the coral against high UV radiation often associated with coral bleaching (e. g. Jokiel 1980, Fisk and Done 1985, Gleason and Wellington 1993) as UV-absorbing substances such as mycosporine-like amino acids (MAAs) have been detected in coral mucus (reviewed by Dunlap and Shick 1998).

Coral mucus may play an important role in providing various defence capabilities against pathogenic organisms (reviewed by Brown and Bythell 2005). During bleaching, corals are in a state of stress owing to energy shortage and damaged epithelia, and thus are more vulnerable to pathogens which may occur with increased abundances at elevated temperatures. Increased mucus release may be a response to decrease vulnerability and support defence against pathogens.

Recent research revealed that azoxanthellate cold water corals release POM in comparable quantities to zooxanthellate warm water corals (Wild et al. in press). This indicates that the release of mucoid exudates by corals is largely decoupled from the presence of zooxanthellae and thus represents a general response to any kind of environmental stress, including bleaching.

Hemichordata: Enteropneusta (Acorn worm) bioturbation: Maintaining and facilitating the balance of coral reef biogeochemical cycles

K.K. Takagi[1], I.S.S. Mchenga[1], M. Tsuchiya[2]

1) Univ. of the Ryukyus, Grad. School of Eng. and Sci., 1 Senbaru, Nishihara, Okinawa, 901-0213, Japan
2) Univ. of the Ryukyus, Faculty of Science, 1 Senbaru, Nishihara, Okinawa, 901-0213, Japan

Abstract. In Bise, Okinawa, Japan, acorn worms inhabit the sandy beach, seagrass and coral/seagrass environments. As such, we assert that its bioturbation behavior aids in "biopurifying" and impoverishing the coral reef ecosystem in regards to nutrients and organic matter. Through the use of fatty acid (FA) biomarkers, C:N, and nutrient analysis, we analyzed tissues of two acorn worm species (*Ptychodera* sp. and *Schizocardium* sp.) and sediments from areas inhabited by, not inhabited by, and fecal casts of the acorn worms. Seawater samples from inhabited and not inhabited areas were analyzed for total nitrates and ammonium concentrations. FA biomarkers of acorn worm tissues indicate significant differences in diatom and plant matter consumption by the two species. In addition, acorn worms assimilate 'reactive' organic matter in the beach habitat. A significant decrease in the beach sediment overall nitrate concentration indicates acorn worm presence mitigates the release of nitrates into the water column and sediments. As the overall FA contribution and TOC contents changed little in the seagrass and coral/seagrass environments, the acorn worm demonstrates the ability to "biopurify" by subtracting "nutrient rich" organic matter, thus facilitating the maintenance of the biogeochemical balance within the coral reef ecosystem.

Key words: acorn worms, biogeochemical cycles, bioturbation, coral reef, fatty acids

Introduction

Maintaining energetic balance is essential for ecosystem function. In addition, as sediments represent the largest physiographic zone, the metabolism of benthic processes tends to dominate the coral reef ecosystem (Rasheed et al. 2002; Gattuso et al. 1998). Thus, bioturbators, which modify the sediments and directly impact benthic processes, subsequently affect the immediate, local, and ecosystem level bioenergetic cycles (Reise 1985; Tenore 1988).

In addition, as sandy beaches have been shown to act as "environmental purification systems" in coral reefs (Tsuchiya et al. 1999), and few species occupy the entire tidal gradient (Reise 1985), it is possible that deposit feeding bioturbators such as the acorn worm (Hemichordate: Enteropneusta) function as biological purifiers in the coral reef ecosystem. Thus, by assessing the role of the acorn worm, it is possible to better understand the overall impact of an organism on the biogeochemical cycles within this system.

In this study, the interactions between bioturbation and the biogeochemical cycles within the coral reef ecosystem are examined using the acorn worm.

Materials and Methods

This study was conducted in Bise, in the northern part of Okinawa Island, Japan (127° 52' 46" N, 127° 52' 43" E) from autumn 2006 to autumn 2007. The intertidal zone is characterized by beach, seagrass, and mixed coral/seagrass, habitats which are exposed during low tide. The dominant coral species is *Montipora digitata.* In addition, the dominant seagrass species is *Thalassia hemprichii.* Based on evidence of fecal cast production, acorn worms were observed at densities of up to 24 individuals m^{-2}.

Schizocardium sp. and *Ptychodera* sp. tissue samples were collected during spring and fall 2007. Sediment and water samples were collected during low tide from the beach (BE), seagrass (SG) and coral/seagrass (CS) habitats, during fall (October-November) 2006. In each habitat, the top 0.0-0.5cm of sediment was sampled with a small plastic spoon. Samples were collected from: surface sediments uninhabited (UN) by the acorn worm, surface sediments next to the fecal cast (NX, <10cm diameter from the fecal casts), and fecal casts (FC, entire fecal casts were collected). All samples were placed in plastic bags and immediately put on ice. Sediments were stored under -40°C until analysis.

Water samples, were collected from two areas within each habitat: uninhabited (UN) and inhabited (HB) by the acorn worm. 250mL of water were collected just above the sediments in the same areas. To prevent the alteration of seawater nutrients due to oxygen presence, the polyethylene bottles were opened, capped underwater and immediately put in ice and transported to the laboratory. Samples were then frozen (at -20°C) until analysis. Analysis was conducted within 24 hours of sampling.

Prior to analysis, all sediment and tissue samples were freeze-dried (FRD-51, IWAKI, Japan). Total Organic Carbon (TOC) and Total Nitrogen (TN) analysis sample preparation was carried out following the methods of Yamamuro and Kayanne (1995) for sediment samples. Analysis was conducted using a Shimadzu high sensitivity CN analyzer (Sumigraph NC-80).

Lipid and fatty acid (FA) analyses were conducted following a modified version of Bligh and Dyer (1959) as detailed by Meziane and Tsuchiya (2000). The FA biomarkers utilized for organic matter (OM) source identification are listed in Table 1.

Seawater and extracted sediment samples were analyzed for nitrate, nitrite and ammonium

Table 1. List of the FA markers used and associated OM sources identified.

Fatty acid (s)	Signature organism (OM source)
15:0 and 17:0 (*iso* and *anteiso*), 18:1ω7	Bacteria
18:2ω6, 18:3ω6, 18:3ω3	Green macroalgae
20:5ω3	Diatoms
18:4ω3, 22:6ω3	Dinoflagellates
24:0, 26:0, 28:0, 30:0, 32:0	Vascular plants

concentrations (NO_2^-+NO_3^--N and NH_4^+-N, respectively) using an automatic water analyzer (QuAAttro, Bran + Luebbe). Sediment nutrients were analyzed following the procedure outlined by Mulvaney (1996).

Data analysis was conducted using SPSS software (Standard version 11.0.1 for Windows, SPSS Inc., US). Results were considered significant if $p < 0.05$.

Results

Tissue analysis of *Ptychodera* sp. and *Schizocardium* sp. revealed significantly higher SAFAs (saturated fatty acids) and BrFAs (branched fatty acids) in *Ptychodera* sp. tissues. *Schizocardium* sp. tissue showed a significantly higher assimilation of ω3 and ω6 EFAs (essential fatty acids) (fig. 1A). Comparison of the biomarker composition of each species indicated similarities in the food resources, yet significant differences in the proportions assimilated. *Ptychodera* sp. assimilated a higher proportion of vascular plants while *Schizocardium* sp. assimilated a higher proportion of diatoms (fig. 1B).

The total organic carbon contents did not vary significantly within the beach and coral/seagrass habitat areas. In the seagrass habitat, the total organic matter (g m^{-1}) content was significantly greater in fecal casts of acorn worms than in areas uninhabited by acorn worms (ANOVA, $F = 5.3$, df = 2, 8, $p < 0.05$). Although not significant, the total amount of FAMEs tended to decrease in the fecal casts of the beach and coral/ seagrass habitats (data not shown).

In all habitats and sediment areas, saturated fatty acids (SAFAs) contributed most abundantly (between 70.1% and 45.3%) followed by monounsaturated fatty acids (MUFAs), (23-38.7%, fig. 2). Palmitic acid, 16:0 was consistently the most abundant individual FA (30.7-56.5%), followed by 16:1ω9 (18.0-30.6%).

In the beach habitat, the MUFAs (ANOVA, $F = 5.6$, df = 2, 8, $p < 0.05$), polyunsaturated fatty acids (PUFAs) (ANOVA, $F = 40.5$, df=2, 8, $p < 0.001$), and essential fatty acids (EFAs) (ANOVA, $F = 50.7$, df = 2, 8, $p < 0.001$) showed a significantly lower percent contribution to fecal cast sediments in comparison to uninhabited and next to fecal cast sediments (fig. 2A). SAFAs however, showed a significantly greater contribution (ANOVA, $F = 46.8$, df = 2, 8, $p < 0.001$).

The seagrass habitat however, only showed significantly lower contributions of PUFAs and EFAs in fecal cast sediments (fig. 2B ANOVA, $F = 11.2$, df = 2, 6, $p < 0.01$ and $F = 11.3$, df = 2, 6, $p < 0.01$, respectively). In contrast, the MUFAs, PUFAs and EFAs of fecal casts in the coral/seagrass habitat did not change significantly. Instead, the branched fatty acids (BrFAs) and long-chain fatty acids (LCFAs) showed significantly lower contributions (ANOVA, $F = 18.3$, df = 2, 6, $p < 0.01$ and $F = 6.5$, df = 2, 6, $p < 0.05$, respectively) while MUFAs showed a significantly greater contribution (ANOVA, $F = 11.1$, df = 2, 6, $p < 0.05$) in comparison to uninhabited sediments (fig. 2C).

However, in assessing the FA biomarkers (data not shown), the beach area showed a significantly lower contribution of green macroalgae and the diatom marker 20:5ω3 (eicosapentaenoic acid) in the fecal cast sediments (ANOVA, $F = 69.8$, df = 2, 8, $p < 0.001$ and $F = 56.6$, df = 2, 8, $p < 0.001$, respectively).

Although bacterial FAs did not show any differences in percent contribution to the FAMEs composition overall, the individual FA, 15:0*a* showed a significantly greater contribution in the fecal cast sediments (ANOVA, $F = 30.7$, df = 2, 8, $p < 0.01$). In contrast, the bacteria markers within fecal cast sediments of the seagrass habitat showed a

significantly lower contribution in comparison to uninhabited and next to fecal cast sediments (ANOVA, F = 37.6, df = 2, 6, p < 0.001). Green macroalgae and vascular plant markers also showed significantly lower contributions in fecal casts as compared to next to fecal cast and uninhabited areas respectively (ANOVA, F = 6.7 df = 2, 6, p < 0.05 and F = 15.4, df = 2, 6, p < 0.01).

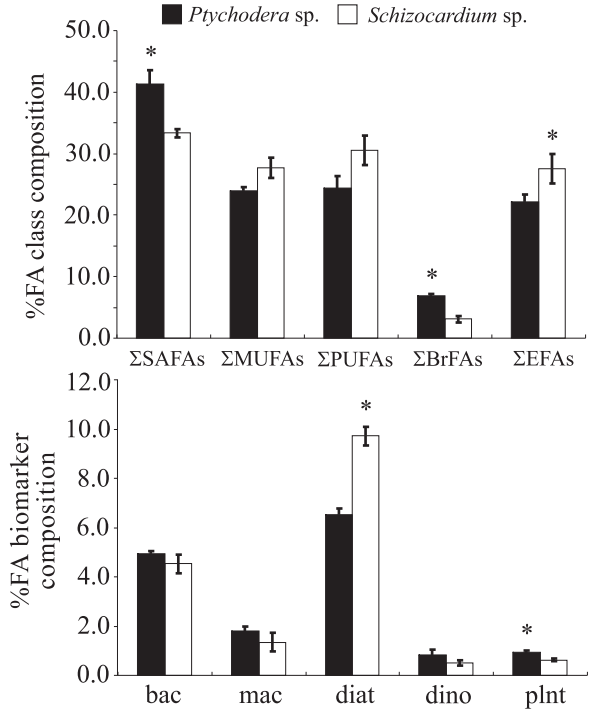

Figure 1. Fatty acid class (A) and biomarker (B) composition comparison between *Ptychodera* sp. and *Schizocardium* sp. tissues. Biomarkers are: bacteria (bac), macroalgae (mac), diatoms (diat), dinoflagellates (dino), and vascular plants (plnt). Values are averages ± SE. * indicates a significant difference, Mann-Whitney, p<0.05.

The decreases in FA markers within the coral/seagrass habitat were not consistent with either the beach or seagrass habitats. Similar to the seagrass habitat, the bacteria markers showed a significantly lower contribution in fecal cast sediments (ANOVA, F = 46.1, df = 2, 6, p < 0.001). In addition, the comparison to the other two sediment areas vascular plant markers also showed a significantly lower percent contribution to fecal cast sediments in comparison to uninhabited areas (ANOVA, F = 11.1, df = 2, 6, p < 0.05). However, although the dinoflagellate markers made up less than 1% of the overall FAMEs composition in each area, a significantly lower contribution was also seen in comparison to uninhabited sediments (ANOVA, F = 8.8, df = 2, 6, p < 0.05).

NO_2^-+NO_3^--N (hereafter referred to as NO_3^- or nitrate) and NH_4^+-N (ammonium) concentrations in seawater just above sediments uninhabited by the acorn worm and just above fecal casts of the acorn worm did not vary significantly in all habitats. However, nitrate concentrations tended to be higher than ammonium in all areas (0.05-3.05μmol l^{-1} and 0.09-0.68μmol l^{-1}, respectively). Nitrate tended to show a lower concentration in the seawater above fecal casts in all habitats whereas ammonium concentrations were slightly greater only in the coral/seagrass habitat.

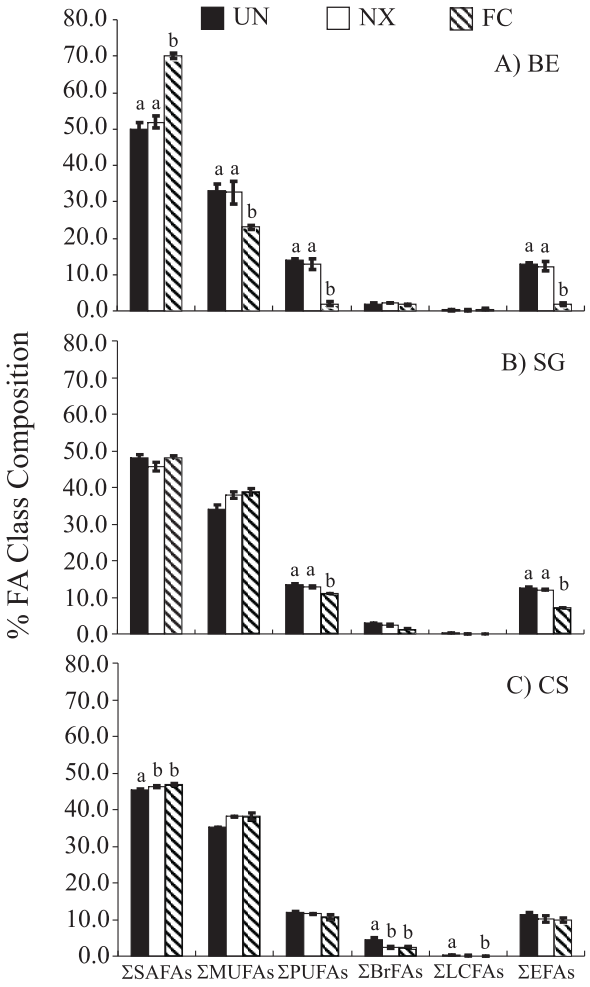

Figure 2. Habitat comparison of the percent FA class composition in the beach, seagrass, and coral/seagrass habitats between uninhabited (UN), next to fecal cast (NX) and fecal cast (FC) sediments. Values are means ± SE, lower case letters indicate significance between areas (ANOVA, p < 0.05).

In contrast, in regards to sediment nutrient content, the beach habitat showed a significantly greater concentration of ammonium than nitrate in fecal cast sediment samples (fig. 3). Here, the nitrate concentration significantly decreased in a step-wise manner from uninhabited to next to fecal cast and fecal cast sediments (fig. 3A, ANOVA, F = 279.8, df = 2, 6, p < 0.001) and the ammonium concentration

was significantly greater in fecal cast sediments (fig. 3B, ANOVA, $F = 483.6$, df = 2, 6, $p < 0.001$). In the seagrass habitat, a decreasing trend is seen in the both the nitrate and ammonium concentrations. However, the concentrations in the coral/ seagrass habitat did not vary significantly between areas.

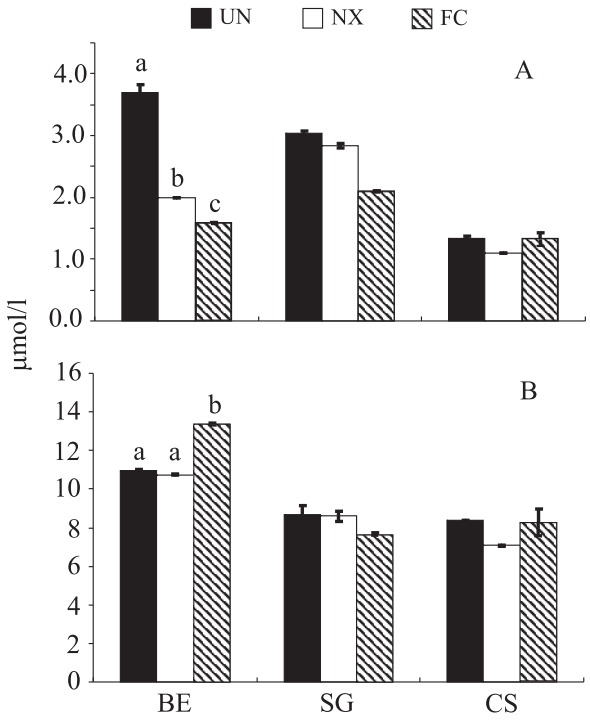

Figure 3. Area comparison of the sediment (A) nitrate and (B) ammonium concentrations in the sediments uninhabited by (UN), next the fecal casts (NX) and the fecal casts (FC) of acorn worms in the beach (BE), seagrass (SG) and coral/seagrass (CS) habitats.

The total nitrogen (TN), total organic carbon (TOC), carbon: nitrogen ratio (C:N) and total organic matter (TOM) contents in the sediment areas of the beach, seagrass and coral/seagrass did not vary significantly within all habitats.

Discussion

Tissue analysis of *Ptychodera* sp. and *Schizocardium* sp. reveals that both species primarily assimilate diatoms, followed by bacteria and macroalgae. However, significant differences in the proportions of diatoms and plants assimilated into the tissues indicates that, on a fine-scale, the impact of an acorn worm on the surrounding environment is species specific.

However, on a large-scale, the impact on the organic matter and nutrient cycles may be similar. The overall FAMEs and significant changes in OM composition exemplify the ability of the acorn worm to assimilate and biologically purify (clean) its surrounding environment, also referred to as biopurification. Similar to earthworms (Lavelle 1988), acorn worms are dependent on external biotic and abiotic parameters. This is confirmed in the inconsistent patterns of FAMEs biomarker composition (i.e. food resources) between the beach, seagrass, and coral/seagrass habitats. However, regardless of the variations due to habitat, the biopurification role of the acorn worm can still be elucidated in the overall "quality" of OM as a result of acorn worm presence. As lipids include essential fatty acids which are utilized by all organisms to maintain bodily function, the absence of EFAs in the fecal cast sediments indicates successful assimilation by the acorn worm. Consequently, the sediment processed by the acorn worm is "stripped," not "enriched" of useful FAs, , and the sediment is of less value to other OM consumers. This exemplifies biopurification.

In regards to dietary fatty acids, organisms in the marine food web have shown preferential assimilation/degradation of PUFAs, resulting in a relative increase of SAFAs (Grossi et al. 2006; Mfilinge et al. 2003). In concurrence with this, the proportional SAFA contribution was significantly higher in fecal cast sediments while PUFAs were significantly lower in the beach habitat. However, the same pattern was not seen in the seagrass and coral/seagrass habitats. Therefore, it is possible that the degradation of PUFAs is due to the preferential utilization by bacteria, rather than the direct assimilation by the acorn worm (Mfilinge et al. 2003). This is also supported by the increased contribution of MUFAs in areas near the fecal cast and fecal casts in the seagrass and coral/seagrass habitats which could instead, indicate an increase in microbial re-colonization on the fecal casts. Therefore, an indirect effect of acorn worm presence on its surrounding habitats likely includes the consequential impact on microbial utilization of nutrients in the sediments and subsequent release and/or upatake in the water column.

In addition, due to the anoxic nature of sediment, nitrate concentrations are expected to be high and ammonium low (Kogure and Wada 2005). This is exemplified by the results from each habitat. However, as the beach environment lacks the dynamics and respiration from corals, plants and other substrates, the significant decrease in nitrates and significant increase in ammonium in the fecal cast sediments clearly indicates the effects of the acorn worm presence. As such, the microbial ammonification activity in the beach habitat seems more enhanced in fecal cast sediments than in the sediment areas in the seagrass and coral/seagrass habitats.

Kogure and Wada (2005) pointed out that, although bioturbation enhances the exchange of water and

oxygen between the water column and sediment, the fecal casts of the bioturbators often remain mainly as reduced environments. Thus, if the acorn worm fecal casts contain micro-anoxic environments then the release of nitrate back into the water column would be limited by the denitrification processes occurring in reduced fecal cast environments. This indirect effect of the acorn worm presence is seen in the decreased concentrations of nitrates in the water column just above the fecal casts in the beach and seagrass habitats. Thus, perhaps a greater part of the bioturbated nitrogen in acorn worm habitats remains within the fecal casts and sediments while a lesser part is oxidized and returned to the water column.

Tenore (1988) stated that the microbial recycling of fecal material (coprophagy) allows further degredation of egested materials making re-ingestion by other organisms possible. This would result in the net increase in nitrogen and nutritional content of detritus. However, as TN concentrations remained relatively the same throughout each area, and the FA compositions showed an overall decrease in EFAs, the acorn worm fecal casts do not increase the sediment nutritional content and therefore do not encourage re-ingestion by subsequent trophic levels. Yet maintenance of the oligotrophic environment is enhanced.

The impact of bioturbators within an ecosystem is two-fold. In the case of the acorn worm, there is a direct and immediate impact on its environment based on its burrowing behavior, sediment ingestion and subsequent production of fecal casts. This "cleansing" effect is its biopurification ability. However, it also has an indirect, chronic impact on its environment based on the degradation of fecal casts over time as well as the changes in microbial dynamics as a result of acorn worm activity and presence. In addition, as acorn worms and most deposit feeders are dependent on their external, abiotic environments for resources, their subsequent influence on the environment will change depending on the season and organic matter inputs. Thus, to further understand the role of the acorn worm in the coral reef ecosystem, it is important to consider how the chronic presence of the acorn worm impacts the surrounding habitat. Studies concerning seasonal changes, acorn worm fecal cast degradation over time, microbial activity as a result of acorn worm presence, and changes in organic matter and nutrient dynamics at depth in the sediment should be conducted to further clarify the direct and indirect impacts of this bioturbator in the coral reef environment.

Abstract. Coral symbiotic complex was investigated with a new approach for sampling and measurements of vitamin B12 and bacteria abundances in the coelenteric fluid. Sampling procedure consisted in the introduction of a glass capillary using a micromanipulator into the mouths of the coral polyps, *Galaxea fascicularis,* under anesthesia and aspiration of the fluid using a vacuum pump. 0.5 to 1 ml of coelenteric fluid could be sampled by aspiration of the fluid of around 20 polyps. Flowcytometry for the measurement of bacteria abundances and radioassay with ^{57}Co labeled vitamin B12 for the measurement vitamin B12 with a minimum volume, were used. Detection limit of the radioassay was 35 pmol l^{-1} with a volume of sample of 0.4 ml. High abundances of bacteria with order of magnitude of 10^7 cell ml^{-1} and high concentrations in vitamin B12 with ranging 100 to 700 pmol l^{-1} were found in the coelenteric fluid, compared with those in surrounding water. Such approach provides a new view on the internal cycling of chemical and biological components in coral reefs. Our study it suggested that coelenteric bacteria produce vitamin B12 and that inner coral forms a semi-closed system.

Key words: Coelenteric Fluid, Radioassay, *Galaxea fascicularis*, Vitamin B12.

Introduction

Coral is described as a symbiosis among an animal, *Cnidarian*, a photosynthetic organisms, the dinoflagellate *Symbiodinium* also known as zooxanthellae, and more recently, the associated prokaryotes. The two first components of this symbiotic complex are widely accepted however the last one is now under focus. Thus coral and zooxanthellae interactions have been studied for a long time. The different methods applied for these studies included the use of carbon isotopes as tracer and separation of host cells and zooxanthellae by detaching the tissue from the skeleton and centrifugation (Muscatine 1990). These classic techniques however totally omitted the associated prokaryotes. Therefore even if associated prokaryotes were the subject of several publications most remain descriptive (Ducklow and Mitchell 1979; Rohwer et al. 2001; Rohwer et al. 2002; Kellogg 2004; Klaus et al. 2004; Bourne and Munn 2005; Koren and Rosenberg 2006; Lampert et al. 2006) and few described the mechanisms of the interactions among prokaryotes, the coral and the zooxanthellae (Herndl and Velimirov 1986; Shashar et al. 1994; Reshef et al. 2006; Rosenberg et al. 2007; Siboni et al. 2008). This lack of knowledge is partly due to the lack of methodology and to the only recent gain in interest.

Corals belong to the taxum Coelenterata and are characterized by the presence of a coelenteron which can be compare to a stomach cavity with only one aperture (i.e. the mouth). Moreover all polyps of one colony are connected together through tubes running through the coenosarc (Gladfelter 1983; Blackstone 1996). The coenosarc is composed of three tissue layers: the epidermis, the mesoglea and the endodermis. The last one is separated from the skeleton by a thin calicoblastic tissue (Goldberg 2002). Therefore coelenterons of polyps from the same colony seems to be connected together. The fluid inside the coelenteron contains, named here as "coelenteric fluid" could be shared by all polyps and is in contact with the surrounding water throughout the mouth. These observations lead to the concept that the coelenteron, the inner coral, could be considered as a semi-closed system. Furthermore zooxanthellae are known to be principally distributed in the endodermis, close to the coelenteric fluid. After all this consideration it is easy to understand the importance of studying the processes occurring in the coelenteric fluid.

In order to study coelenterate nutrition Porter (Porter 1978) described a technique to sample the coelenteric fluid of corals. On another hand Herndl et al. (Herndl et al. 1985)following Porter's method

sampled the coelenteric fluid of a giant anemone and reported for the first time the presence of bacteria living in the coelenteron. However the technique used in these two papers is not applicable directly to corals bearing small polyps as it was designed for *Montastrea cavernosa* and later applied to Giant anemone.

Here we focused our studies on the methodology required to investigate the role of the coelenteric bacteria. In order to consider as strictly as possible the processes occurring in the coelenteron we modified Porter's method to sample coelenteric fluid of small polyps corals. Also we chose vitamin B12 to investigate the linkage between the coral and the bacteria. Vitamin B12 is known to be only produced by prokaryotes. Moreover vitamin B12 is known to be required by all animals and by the majority of phytoplankton. The requirement of zooxanthellae for vitamin B12 was checked (Agostini et al., in press) and it was found that zooxanthellae were vitamin B12 dependent. For this study, measurements of vitamin B12 required the development of a new methodology with high sensitivity and requiring a low volume of sample. Determination of coelenteric bacteria abundances were done using flow-cytometry as it can be used on low volume samples. The different techniques developed and applied here are presented.

Material and Methods

Tests organisms

The coelenteric sampling technique was tested on different coral species in order to select the most suitable one. All coral colonies were taken from the reef in front of Sesoko Station, Ryukyu University, Okinawa Japan, and kept at the station in an aquarium with continuous flow of sea water. The different species tested were: *Galaxea fascicularis* (Linnaeus 1767), *Fungi fungites* (Linnaeus 1758), *Favites chinensis* (Verill 1866), and *Montastrea curta* (Dana 1864).

Coelenteric sampling

A specimen was transferred to a smaller aquarium at the time of sampling. To avoid retraction of the polyps during sampling, some corals were anesthetized using menthol (Moore, 1989). Anesthesia was done by scattering ground crystals of menthol on the surface and putting the aquarium in dark for about 45 min (depending on the species and size of the specimen and aquarium). Coral could be kept insensitive for 3 hours, until water was changed. After water change, the corals recovered quickly and therefore several anesthesia could be done in one day without any harm. Coelenteric fluid was sampled using a glass capillary mounted on a micromanipulator (Sutter Instrument model MM-33) under zoom stereomicroscope. Capillary used for the sampling was made from glass pipe and its external diameter was of less than 1 mm. The diameter should be adjusted to the polyp size. After introduction of the capillary into the mouth, the gastric content is gently sucked using a vacuum pump (max vacuum of 0.09 Bar). The fluid was collected into an HCl washed sampling tube kept in the dark during the time of sampling. Tubing connecting the capillary to the sampling tube were silicon tubes HCl washed before setup of the apparatus and between consecutive sample the tubing was washed by aspiration of MilliQ water. The volume collected by this method was of 0.5 to 1 ml after anesthesia and by sampling around 20 polyps of the same colony.

Radioassay of vitamin B_{12}

It was commonly used for determination of the level of vitamin B12 in human blood (Houts and Carney, 1981) and an attempt to use it on sea water was done by using another binder to decrease the detection limit (Sahni et al. 2001). The method used in this study was based on competitive binding radioassay using the binder and tracer from the commercial kit Simultrac-SNB (MP Biomedicals). It was optimized for seawater and required less than 0.5 ml (measurement in duplicates) of sample. Standards were done in vitamin B12 free seawater. Some samples were boiled for 30 min to check that no endogenic binder interfere with the assay. After optimization the following protocol was chosen: samples (200 µl) were incubated with 50 µl of [^{57}Co] labeled cyanocobalamin and 750 µl of Binder (purified porcine intrinsic factor bound on a solid support) for 2 hours at constant temperature and gently shaken. After centrifugation at 1000 g for 10 min, the supernatant was discarded and the pellet radioactivity was counted during 5 min using a gamma counter (Aloca, ARC-380, Tokyo Japan) set up for [^{57}Co] with a window of 100-180 KeV. Concentrations were read against standards, made with pure cyanocobalamin (Sigma Aldrich) in vitamin B12 free seawater, plotted with a logit-log scale.

Affinity of the binder in seawater was investigated by saturating aliquots of the binder with increasing amount of labeled cyanocobalamin (MP Biomedicals). Kinetics of the reaction was also investigated to determine the optimum reaction time and conditions. Incubation was done in two different conditions: at room temperature, not shaken and in a water bath at 25°C gently shaken.

Bacteria abundance determination.

In order to determine the abundances of bacteria in the coelenteric fluid flowcytometry was used (Monger and Landry, 1993). Bacteria were stained with SYBR-Green and then counted using a Beckman Coulter flow Cytometer. Picocyanobacteria were counted

using the same flowcytometer using their natural fluorescence due to main pigments, phycoerythrine and chlorophyll. Relative size of cells and their fluorescence allowed distinguishing populations of both *Prochlorococcus* and *Synechococcus*.

Results

Coelenteric sampling

Not all species were successfully sampled. Following detailed results by species may help for future applications to other species and further modifications of the technique. Mainly the results depended on the anatomy, size of the polyp.

Fungi fungites: This was the biggest polyp tested. As the polyp did not retract no anesthesia was used. Mouth of the specimen tested was more then 1 cm long and few millimeters wide. After introduction of the capillary the coral opened its mouth and secreted abundant mucus. Therefore the samples collected were largely contaminated in surrounding and freshly secreted mucus.

Favites chinensis: Size of the polyps were of the centimeter order and the mouth was almost as large as the polyp. However the sampling was not successful. First this species expands its polyps only during night time and during retraction the mouth is not accessible. Furthermore it was very sensitive: a light movement and the polyps retracted, so anesthesia in expanded state was not possible.

Montastrea curta: The size of the polyps were of the cm order and the mouth was more than 1mm. The polyp was not sensitive and introduction of the capillary was possible without anesthesia. However, this species secreted a lot of mucus and aspiration was very slow due to the high viscosity.

Galaxea fascicularis: this species was finally chosen for this study. Polyps were around 1 cm large and, depending one the specimen, could be 1 cm high. The mouth was smaller than 1 mm. The polyp was calcified until the oral disk giving it rigidity. Retraction was only of the oral disk and the tentacles which then covered the mouth. To avoid this the coral was anesthetized. The anesthesia time was of 45 min and should be done in the dark to obtain a maximum of expansion. Capillary could be inserted quite deep but it was blocked by internal calcified septum. The volume of coelenteric fluid collected by this technique was of 0.5 to 1 ml, by sampling 20 to 50 polyps in a maximum of 3 hours. Depending on the vacuum used, mesenteric filaments may be aspirated. To avoid this, pressure must be decreased but the volume and speed of collection might decrease. As a rule we limited the pressure to -0.09 Bar, usually collecting at -0.05 Bar and increasing just when necessary.

Radioassay of the vitamin B_{12}

Affinity of the binder in seawater.

Total saturation was not reached with the amount of tracer added, therefore the affinity constant was calculated using the linearisation of Hanes Woolf : the ratio between bound and added labeled cyanocobalamin was plotted against the bound vitamin (Zettner, 1973). Added vitamin was measured before centrifugation and bound in the pellet after centrifugation:

$$\frac{Vit_b}{Vit_a} = Vit_a \times \frac{1}{V_m} \square \frac{K_d}{V_m} \quad (1)$$

with Vit_b being the vitamin bound (in the pellet), Vit_a the vitamin added, V_m the maximum velocity (here the saturation), K_d the dissociation constant. For calculation of the affinity constant cpm were converted to mol l^{-1} using a specific activity of 9.02 10^{17} cpm mol^{-1}. The resulting constant of dissociation was 4.41 10^{-12} mol l^{-1}, thus the affinity was of 10^{11} l mol^{-1} which allow measurement of the picomolar order (Zettner, 1973).

Radioassay detection limit, when defined as 3 times the SD of the trace binding was of 35 pmol l^{-1} which was in agreement with the affinity constant found. The optimum conditions for the incubation were determined to be 2 hours at 25 °C gently shaken.

Coelenteric Fluid Analysis

Bacteria abundances

Flowcytometry was useful for the determination of coelenteric bacteria abundances. It gave reproducible results and required only 30 µl for each measurement. Abundances were always found higher in the coelenteric fluid with 7.5 x 10^6 to 4.6 x 10^7 cell ml^{-1} than those in the surrounding water: 3.54 x 10^5 cell

ml^{-1} for the aquarium water and 3.9 x 10^5 cell ml^{-1} as an average value for the natural surface water. Variations in abundances were observed but no trend, such as diurnal variation, could be observed. Picocyanobacteria (*Synechococcus* spp and *Prochlorococcus* spp) abundances were also measured one time and had a concentration similar to the aquarium water: *Synechococcus* spp : 8.9 x 10^2 cell ml^{-1} (aquarium) and 6.1 x 10^2 cell ml^{-1} (coelenteric); *Prochlorococcus* spp 4.8 x 10^2 cell ml^{-1} (aquarium) and 6.1 x 10^2 cell ml^{-1} (coelenteric).

Vitamin B_{12} concentrations

In the coelenteric fluid concentrations of vitamin B12 ranged from 108 pmol l^{-1} to 704 pmol l^{-1} . Surface water and aquarium water had no detectable level of vitamin B12 by radioassay. The difference of concentrations between coelenteric fluid and surrounding water is of 1-2 orders of magnitude (data not shown).

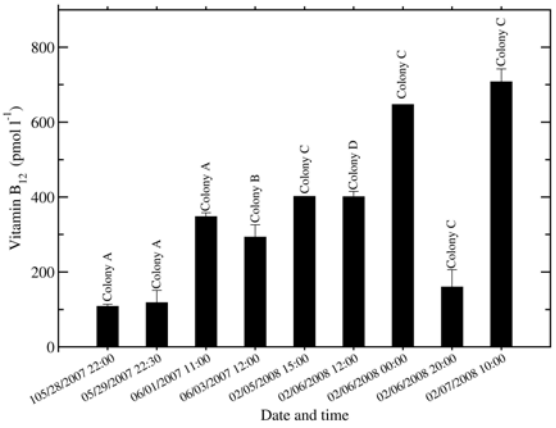

Figure 2: Coelenteric vitamin B12 found in the coelenteric fluid of Galaxea fascicularis. Colony A, B, C and D represent the 4 different colonies used. Error bars represent the standard deviation between 3 measurements.

Discussion

Radioassay allowed the measurement of vitamin B12 in the coelenteric fluid using 400 µl and the concentrations found were high and could be detected. Although the present detection limit was 30 pmol l^{-1}, by using pre concentration of the samples, lower concentrations would be detected but it will require a higher volume. Such pre concentration may be useful for the measure of vitamin B12 in the surrounding water. The affinity found of intrinsic factor, the binder used here, in saline solution (35 g l^{-1} NaCl) do not differs significantly from the one reported for blood analysis (Sahni et al. 2001). Therefore the detection limit was still comparable with the one reported for blood analysis. The affinity of intrinsic factor was reported to be maximum at pH 9 which is closed to seawater pH. Standards should be done in vitamin B12 free seawater and not in MilliQ water as affinity may be different in the two solutions leading to inaccurate concentrations. We considered that the chemical characteristics (especially pH, ionic strength and protein content) of coelenteric fluid and seawater were relatively close and therefore that differences in the affinity of the binder for vitamin B12 between standards and samples were negligible. Affinity may also change with long storage of the binder. The binder was stored in dark at 2-8°C and its stability was of around 3 months. To avoid inaccuracy, a standard curve was realized for each measurement. The original protocol provided by the maker include a step of chemical extraction. Such extraction is required for blood analysis, as in blood the vitamin B12 is bound to its transporter (Houts and Carney, 1981). Moreover the blood endogenic binder may interfere with the assay. In our case no endogenic binder were expected and in order to check their absence some samples were boiled. Such boiling would denature all proteic binder (Rothenberg, 1963). No difference between before and after boiling were noticed suggesting the absence of endogenic binder in our samples. The radioassay methods was also compared to an HPLC methods (Okbamichael and Sañudo-Wilhelmy 2004) and no significant differences for the measure of vitamin B12 concentration in seawater were found (Agostini et al., *in press*).

The sampling of coelenteric fluid of the coral *Galaxea fascicularis* was successful. No contamination from surrounding water seemed to occur as vitamin B12 concentrations and bacteria abundances differed widely. To ensure that no contamination occurred, the capillary was inserted as deep as possible and if deep insertion was not possible, aspiration was not done. Suspect samples, i.e. high volume of fluid aspirated in short time, were discarded. Vacuum pressure should be kept as low as possible to avoid aspiration of mesenteric filament and so lesion of coral tissue. However a too low pressure did not allow the collection of a sufficient volume in a reasonable time and the pressure was sometimes increase to a maximum of 0.09 Bar. Some samples required as much as 3 hours for their collection. Three hours seemed to be the maximum time for which we could keep the coral in the same water and under anesthesia. A longer time of sampling had several consequences: the coral started to show change of the color of the tissue, stability of the samples at room temperature may not be good, production or consumption by coelenteric bacteria of vitamin B12 may occur in the sampling tube. Finally a too long sampling time decrease the time resolution of the technique. In this report all time of sampling indicated the time at which the coral colony was transferred to a smaller aquarium for sampling. A shorter time of sampling may be

obtained by selecting a coral species with bigger polyps but the risk of contamination from surrounding water would increased as it happened when the coral *Fungia fungites* was tested.

Coelenteric high abundances in bacteria and high concentrations in vitamin B12 lead to 2 conclusions: (1) the coelenteric bacteria seem to produce the vitamin B12 required for the growth of the coral and symbiotic zooxanthellae. (2) the coral forms a semi-closed system enabling high concentration of essential nutrients that are scarce in the surrounding water. The concept that coral forms a semi closed system, as it was suggested by their anatomy, was confirmed by the difference between internal (inside the coelenteron) and external (in the surrounding water) vitamin B12 and bacteria abundances. Further discussion on this concept will be done elsewhere (Agostini et al*.,* in preparation).

The radioassay as described in this report provided an easy, accurate and fast way to measure vitamin B12 in a minimum of volume. Sampling of coelenteric fluid of alive coral followed by chemical and biological analysis allowed the study of the processes occurring in the coelenteron. Here we show the application of radioassay for the measure of vitamin B12 and of flowcytometry for the measure of bacteria abundances but an exhaustive description of the coelenteric fluid, biological and chemical characteristics may be required for further understanding of the relations among the different component of the coral symbiotic complex.

Abstract. Model experiments of a recycling-oriented shrimp aquaculture using natural ecological function of benthic and planktonic organisms were carried out in Samut Songkhram, the Gulf of Thailand. Water and sediment qualities in the system deteriorated during shrimp aquaculture due to the wastewater of shrimp culture. Approximately 70-75 % of nutrients were purified when water circulated and up to 2.8 kg phosphorus and 48 kg nitrogen were reduced by means of the recycling-oriented aquaculture system. Survival rate and production of shrimps were the highest in the water circulated system. Total production of the water circulated system was approximately 30 % larger than that of the closed system and, as the results, the feed conversion ratio improved about 10 %. A total of 42 species/taxa of macrobenthic organisms, mainly Annelida, Mollusca and Arthropoda, were identified and we selected species suitable for inhabit the recycling-oriented aquaculture system. The recycling-oriented aquaculture system utilizing natural ecological functions of organisms was a feasible technology for sustainable aquaculture, although further investigation should be needed.

Key words: giant tiger prawn, *Penaeus monodon*, sustainable aquaculture, macrobenthos, Thailand

Introduction

In the Gulf of Thailand, shrimp aquaculture in coastal areas has rapidly developed and expanded since the middle of the 1970's, and the production of cultured shrimps has increased drastically (DOF 2003; Barbier *et al* 2004). During the 25 years from 1975 to 2000, shrimp farming areas increased from 129 km^2 to 811 km^2 and the number of farms increased largely from 1,544 to 34,979 (DOF 2003). The excessive intensive utilization of coastal areas has resulted in the destruction of many mangrove ecosystems and water pollution affecting the culture ponds and adjacent coral reefs. Recovery of mangrove ecosystems is of utmost importance for restoring the productivity of the coastal aquaculture and fisheries (Hogarth 1999; Barbier *et al* 2004).

In order to develop a rational and sustainable utilization strategy for mangrove ecosystems, we constructed a model plant of recycling-oriented aquaculture system in which environmental loading has been reduced due to the natural ecological functions of native organisms such as macrobenthos, plankton, algae, seagrass, mangrove trees, and so on. In this study, we demonstrated one of the experiments of shrimp culture to evaluate performance of the recycling-oriented aquaculture system.

Material and Methods

Model experiments of shrimp aquaculture by means of the recycling-oriented aquaculture system were carried out in experimental ponds of Samut Songkhram Fisheries Research Station (13°26.3'N, 100°03.5'E), Kasetsart University, along the Gulf of Thailand (Fig. 1). The aquaculture system consists of five main modules (see Fig. 4); that is, shrimp culture ponds, inlet channel, outlet channel, water treatment pond and reservoir pond. Every shrimp culture ponds were 40 m x 20 m in the upper area, 35 m x 15 m in the bottom area and 1 m water depth. The inlet and the outlet channels were about 400 m x 5 m, and the water treatment pond was 80 m x 80 m with convoluted water pathway. Area of the recycling-oriented aquaculture system from the outlet channel to the inlet channel was approximately 8,500 m^2 including the water treatment pond. Mangrove saplings, *Rhizophora mucronata* Lamarck were planted into outlet channel, water treatment pond and two shrimp culture ponds. Selected various kinds of benthic organisms (mollusks, polychaetes, algae, *etc.*) were selected and cultured depending on characteristics of every modules.

The experiments were started on February 25, 2005 with shrimp fry of 15 days of age (PL15) and cultured for 160 days until August 3, 2005 (Fig. 2). 13,000 fry

of the giant tiger prawn (*Penaeus monodon* Fabricius) were stocked in each of 3 ponds (Ponds 1, 3 and 6) with a density of approximately 20 individuals per square meter (m^2), and 6000 fry in a mangrove planted pond (Pond 4). In Pond 1 and Pond 4, the water was pumped out biweekly into the outlet channel and supplied from the inlet channel through the water treatment pond. The control of the experiment was Pond 2, where no shrimps were cultured. Pond 3 was a closed intensive aquaculture without exchange of the water.

Water temperature, salinity, dissolved oxygen (DO), hydrogen-ion concentration (pH) and turbidity were monitored by means of data logger and water quality checker. Nutrient concentration were analyzed by standard methods (Eaton *et al* 1995) using a spectrophotometer and a fluorometer. Benthic organisms were quantitatively core sampling method and line intercept transect (LIT) method.
